SCIENTIFIC WORTHIES.

XXX.—STANISLAO CANNIZZARO.

IN the autumn of last year there occurred in Rome an event which attracted the attention of the whole scientific world, and more especially of that portion of it which is concerned with chemistry. The occasion was the celebration of the seventieth anniversary of the birth of Prof. Stanislao Cannizzaro, Senator of the Kingdom of Italy, and Professor of Chemistry in the University of Rome. The pages of this journal have already borne witness to the feelings of esteem and gratitude which that event evoked. At the public meeting called to do him honour, all the learned bodies in the world which have any concern with science, or have any regard for its welfare, combined to offer their felicitations, and vied with each in the warmth of their expressions of appreciation and good will, and a multitude of letters and telegrams were received from chemists in all parts of Europe and America. The place of honour in the list of the addresses, as enumerated in the interesting account of the ceremony since published, is given to that from the Royal Society, which repeated the terms in which the Council had previously made known to Prof. Cannizzaro its reason for awarding him the highest distinction in its power. Next comes that from the Chemical Society, which recalls with pride that the name of Cannizzaro has given lustre to the roll of its foreign members for more than half the period of his life-time.

In what follows we desire to give an account of the life and labours of one whom men of all nations have thus shown themselves eager to honour.

Stanislao Cannizzaro, the fourth and youngest son of Mariano Cannizzaro and Anna Dibenedetto, was born on July 13, 1826, at Palermo, where his father was a magistrate, Director-General of the Sicilian Police, and subsequently President of the High Court of Chancery. The future chemist was educated partly at home and partly at the normal school of his native city, and on the death of his father in 1836, he was placed in the Carolino Calasanzio College. The cholera epidemic of 1837 ravaged Palermo, the young Cannizzaro lost two of his brothers, he himself was attacked by the terrible scourge, and it was only after a tedious convalescence that he was able to resume his studies. Elementary education in Sicily at that time was wholly under the control and direction of the priests: grammar, rhetoric, poetry and philosophy, with a very small modicum of mathematics and geography, constituted the pabulum on which the youth of the period was fed. The physical sciences, of course, had no place in a system which was essentially mediæval. The boy soon gave evidence of his power, and after a school career of distinction he entered, in 1841, the University of Palermo with the intention of devoting himself to medicine.

The subject, however, proved uncongenial, and the youth tried in vain to pass the necessary examinations. Stimulated, however, by Foderà, who at that time taught physiology in Palermo, and with whom the young student became intimately acquainted, he was led to take up experimental work in connection with chemical physiology. It is needless to say that at this period Palermo possessed no laboratory accommodation, and all the manipulative essays that the young experimentalist could venture upon had to be done at his home, and with such improvised appliances as he could command. In the autumn of 1845 he went to Naples, where he came in contact with Melloni, the most eminent Italian physicist of his time, with whom he contracted a warm friendship. Mainly through the recommendation of Melloni, who quickly learned to appreciate the character and power of his young friend, Piria, who is honourably known to chemists by his researches on plant products, was led to offer the young Sicilian the post of *préparateur* in the chemical laboratory of the University of Pisa. To Pisa accordingly he went, and the step decided his career. What Melloni was to physics in Italy at that period, Piria was to chemistry. The young assistant could have had no better master. Raffaele Piria, then in the full tide of his vigour, was an admirable, albeit a most exacting teacher. A distinguished pupil of Dumas, and a remarkable expositor, his lectures were distinguished by the same love of method, of orderly arrangement, of

precision, neatness, and even elegance that characterised his laboratory work; and Cannizzaro and his fellow-assistant Bertagnini must at times have been sorely exercised to satisfy the rigorous ideal of exactitude and of manipulative skill required by the Professor in the experimental illustration of his lectures. When not employed in the class-room, his duty was to wait on Piria in the laboratory. Piria during that period was engaged upon those inquiries on salicin, populin, asparagin, and their derivatives, by which he is best known to the chemists of this time. The greater part of the experimental labour connected with these investigations was done by Piria himself during the eight hours that he daily spent in his laboratory, Cannizzaro being for the most part, as he says, a simple looker-on, observing attentively and in silence the rare skill and manipulative ability with which the work was executed. Occasionally, however, the assistant would be called upon to continue some experiment or analysis which Piria had begun, or to prepare some material he needed; all of which he was required to perform in literal compliance with the instructions he received from the master. Most of the work of preparation in connection with the lectures had to be done in the early morning, before Piria descended from his apartments to the laboratory. These preparations were carefully scrutinised by the Professor, who would tolerate no slovenliness or negligence, and whose æsthetic sense demanded that the apparatus should not only work well but look well. Although a silent worker during the day-time, and a most severe judge of his assistant's duty whether in the laboratory or in the lecture-room, Piria could unbend in his hours of ease, and many an evening was spent by Cannizzaro with his master, who would then freely discuss chemical subjects with his young assistant, and explain the object and meaning of the work on which he had been engaged during the day.

This severe discipline, to which Cannizzaro frankly confesses he owes much of the success of his after-career as a chemist, was interrupted by events, which, as they have turned out, had no small share in determining also his success in his career as a politician. Returning to Sicily at the end of July 1847, presumably to spend his vacation at home, the ardent young Liberal of twenty-one, mindful of the events of 1836, naturally found himself in active sympathy with the movement of the time, and when the revolution broke out in January 1848, he became an officer of artillery at Messina. Having been elected deputy for Francavilla in the Sicilian Parliament, he went to Palermo at the end of March, and, as the youngest member of the Assembly, he was required to act as its Secretary. After the bombardment and fall of Messina on September 7, 1848, he was sent to Taormina to organise resistance to the advance of the royal troops. The armistice of September 13, extorted by the combined fleets of England and France to put a stop to the atrocities of Ferdinand's army, stayed for the moment further hostilities, but Cannizzaro was ordered to remain at his post as Commissioner of the provisional Government. The armistice ended in the following March, and after the disaster of Novara, and with it the abdication of Charles Albert, the Sicilian movement utterly collapsed. The royal troops were everywhere victorious, the insurgents retreated first to Catania and thence by Castrogiovanni to Palermo, and, in May 1849, Cannizzaro, with a number of his compatriots, succeeded in escaping for Marseilles on board the Sicilian frigate *Indipendente*. He was now in exile, and led for a while a somewhat wandering and aimless existence. After a short stay in Marseilles, he passed on to Arles, and visited in turn Avignon, Lyons, Nîmes and Montpellier. In time, however, he again betook himself to his chemical studies, although his means were very limited and his opportunities few. He had, of course, no laboratory, but he read such books as he could obtain, and visited such chemical factories as would admit him. When the body of the unfortunate and broken-hearted Charles Albert was brought back from Oporto, to be buried in the land for whose liberty he had sacrificed his kingship, Cannizzaro joined his fellow-refugees in Turin in order that they might testify by their presence at the obsequies of the dead monarch their grateful memory of his services, and their resolution that his tomb on the Superga should be to them the symbol of an undying aspiration.

Towards the end of October, Cannizzaro found himself in Paris. Thanks to a letter from Piria, he became acquainted with Cahours, who introduced him into the little laboratory of Chevreul attached to the theatre in the Jardin des Plantes, where he found Cloëz installed as assistant. He had now abundant opportunities for work, and with the characteristic ardour of his Southern blood he embraced them all. The excitement of political disquietude in Paris has never seemed to react disastrously on the progress of science there. Curiously enough, for some inscrutable reason, it would appear to stimulate it. Indeed, some of the darkest and most unsettled periods of the political history of France have been among the brightest and most glorious epochs in the annals of science. The stir of 1848, and the unrest which followed it, were contemporaneous with an extraordinary activity in chemical and physical inquiry in Paris, and Cannizzaro participated to the full in the busy movement going on around him. Dumas, it is true, had been swept by his political convictions into the Legislative Assembly, to become Minister of Agriculture and Commerce; and his laboratory in the Rue Cuvier, in spite of the seductive offer of Jecker, was closed.

Still, if Cannizzaro never came under the spell of Dumas, he could witness Fremy's experiments in the laboratory of Gay Lussac, and could attend Regnault's lectures in the Collège de France. But it was to the chemical work-table he mainly turned, and on this he spent the greater part of his time and energies. He took up the study of the amines, the existence of which had recently been made known by Wurtz, and, with Cloëz, prepared cyanamide by the action of ammonia on cyanogen chloride. An account of the nature and properties of this compound, published in 1851 in conjunction with Cloëz, constitutes Cannizzaro's first contribution to the literature of chemistry. The reaction by which they obtained the substance proved exceedingly fruitful, and, by the substitution of amines for ammonia, Cahours and Cloëz subsequently prepared the alkyl cyanamides. Moreover, cyanamide itself, by the ease with which it suffers polymerisation, gives rise to a number of isomeric

series of homologous amides of considerable theoretic interest. Congenial and inspiriting as the atmosphere of Paris might be, man cannot live on air alone. But there were too many young and eager aspirants, of French nationality, for the few posts which practically only Paris was able to offer, to justify the hope that the young Sicilian could obtain a position, sufficiently lucrative even for his modest requirements, in the land of his exile. Piedmont, of all the Italian States, could alone afford an asylum to him, and accordingly, towards the end of 1851, he accepted the position of Professor of Physical Chemistry and Mechanics in the National College of Alessandria, an institution modelled somewhat on the lines of a German Realschule. Here, thanks to the action of the municipality, he was provided with a small laboratory, together with an assistant, and, although much occupied by his public lectures on chemistry and mechanics given to the townspeople, in addition to his regular class instruction, he began the study of the action of alkylamines on cyanogen chloride, only to find himself forestalled by Cloëz and Cahours. At about the same time he discovered benzyl alcohol, which he obtained by the action of alcoholic potash on bitter almond oil, and the properties and modes of decomposition of which he described in a series of letters to Liebig and Wöhler, published in the *Annalen.* His vacations were usually spent with Piria at Pisa, or at Montignoso, near Massa-Carrara, with his old collaborateur Bertagnini, with whom he worked on anisic alcohol (*Ann. de Chimie*, xlvii. 285).

In October 1855, he was called to the chair of Chemistry at the University of Genoa, and at the same time Piria was moved from Pisa to Turin. Although the new position at Genoa was one of greater dignity and emolument, Cannizzaro found himself, so far as laboratory accommodation was concerned, less favourably situated than at Alessandria; the only place at his disposal was a damp and dimly-lighted room, without the slightest convenience for even the most elementary experiments. For some months he found it impossible to carry on the work he had begun at Alessandria. In the following year he obtained a room on the upper floor of the University building, and this, with the aid of an assistant and a couple of pupils, he turned into a fairly convenient laboratory, where he resumed his work on the aromatic alcohols. At Genoa Cannizzaro began the studies on chemical philosophy, which were to culminate in the great generalisation with which his name will continue to be associated. Admirable as his experimental labours are, his chief claim to the esteem and gratitude of his contemporaries and of posterity rests upon his critical contributions to the philosophy of chemistry. In what this signal service consisted will be shown subsequently.

During the whole of this time Italy was in a state of political ferment. The astute Cavour had gradually secured his ascendancy in the parliamentary Councils of the little Sardinian kingdom, and with it his position in the Councils of Europe. Slowly, and in spite of many checks, the cause of Italian unity gained ground. Magenta and Solferino secured Lombardy, and although Victor Emmanuel was forced to give up Savoy, the very cradle of his dynasty, as the price of Louis Napoleon's co-operation, Italy gained Tuscany, Modena, Parma and Romagna; and in 1860 the annexation of Central Italy was complete. Bombino still held his grip on the two Sicilies, but the islanders made one more effort to throw off the hateful yoke. The time seemed propitious, and Palermo, Messina and Catania were soon ablaze; and before the middle of May, Garibaldi and his famous "Mille" had accomplished the liberation of the island. Cannizzaro immediately returned to Palermo. He found here his aged mother and sisters, whom he had not seen since 1849, and at once threw himself into the labour of organising and consolidating the work of the revolution, taking an active part in the debates of the States Council convened to define the relation of Sicily to Italian unity. The affair of Spartivento to all intents and purposes decided the fate of Lower Italy, and by the first week of September Garibaldi was in Naples, and with the shutting up of the last and feeblest of the Neapolitan Bourbons in Gaeta, the emancipation of Italy was practically secured. What remained to be done time would effect.

Cannizzaro now returned to Genoa, passing through Naples, where Piria had been called to reorganise the system of public instruction, and resumed his work at the University. In the preceding March he had been offered, but had declined, the Professorship of Organic Chemistry in the University of Pisa. He was now invited to occupy the chair on the same subject in the University of Naples, and this he also refused. He was then claimed by his native town, and in October 1861, he was named Professor of Inorganic and Organic Chemistry, and Director of the Laboratory of the University of Palermo. What he had to "direct" was contained in a few cupboards, in the same class-room that he had sat in as a student in 1842, and was barely sufficient for even the most elementary illustrations. The whole of the following year was spent in organising his courses and in superintending the arrangement and plenishing of the rooms he ultimately acquired on the top-floor of the University building.

Cannizzaro remained at Palermo for about ten years; he took an active share in the management of the University, and for a time was its Rector. Its influence as a school of chemistry may be judged of from the fact that he had as co-workers Adolph Lieben, Wilhelm Koerner, and lastly Paterno, who has succeeded him in the chair. For the most part he occupied himself, as regards his laboratory work, with the study of aromatic compounds, and in extending and completing his researches on the amines.

If Cannizzaro was useful to the world as a chemist, he was so far mindful of Priestley's example as to strive to be equally useful to Palermo as a citizen, and much of his time and ability was freely given in the service of her municipal government, more particularly on subjects relating to elementary and secondary education.

In 1871 Cannizzaro was called to occupy his present position of Professor of Chemistry in the University of Rome, and Director of the Chemical Institute in the Orto di S. Lorenzo in Panisperma, and here, for the last five-and-twenty years, he has annually delivered his two courses, each of three lectures a week, on general and organic chemistry, and has worked out, partly alone and partly in conjunction with his pupils Amato, Blaserna, Carnelutti,

Sestini, Valente, Fabris and Andreocci, the chemistry of santonin. At the same time that he was called to Rome he was made a Senator of the kingdom, and as a moderate Liberal he has taken his share in the consolidation of the constitution of regenerated Italy.

Cannizzaro, when compared with such men as Berthelot and certain of the leaders of the German schools of chemistry, or even with some of the younger generation of Italian chemists, cannot be called a voluminous writer. In all about eighty memoirs have proceeded from his laboratory. It is on the special quality and character of his published work, rather than on its extent, or on the range and variety of its subject-matter, that his fame depends. In this respect he resembles the late August Kekulé. The names of both men will for ever be associated in the history of chemistry with the promulgation of generalisations which mark epochs in the development of chemical science. Cannizzaro's great merit consisted in being the first to clearly point out the bearing on chemical theory of the hypothesis which is commonly associated with the name of his countryman Avogadro, but which Cannizzaro himself, in his well-known lecture delivered before the Fellows of the Chemical Society in 1872, associated also with the names of Ampère, Krönig and Clausius. This, perhaps, is not the time and the place to discuss the question of whatever claims John Dalton may have to be the first to recognise the fundamental truth embodied in the statement that gases, under comparable conditions, contain in equal volumes equal numbers of molecules, whatever may be their nature and their weight. For the moment we are concerned only with the fact that it remained to Cannizzaro to show that the hypothesis afforded the means of placing the most important of all chemical constants—the atomic weights of the elements—on a definable and intelligible basis, and thereby of rendering our conceptions of atoms and molecules, atomic weight and molecular weight, of gaseous volumes and valency, and of all that is associated with or follows from these conceptions, more logical, consistent, and harmonious. What Cannizzaro did, in a word, was to throw light upon what was obscure, to introduce order where all was confused and contradictory. Hence his "Summary of a Course of Chemical Philosophy," published in 1858, will occupy in the history of chemical doctrine a position as a classic, not less honourable than Dalton's ever memorable "New System." There were, of course, difficulties to be overcome, and inconsistencies to be reconciled: certain facts, indeed, appeared to be hopelessly opposed to the hypothesis which Cannizzaro sought to make the corner-stone of the edifice of modern chemistry. But these difficulties have been gradually swept away, and the very facts which at first seemed incapable of being brought into line, are now seen to afford the strongest support to the truth and universality of the theory.

The theory of Avogadro, indeed, has been approached from independent, although converging standpoints, and its position is now secured by the concurrence of independent testimony. Mathematical conceptions of the nature of gases have shown its necessity. Chemical facts, for a time, were seemingly opposed to it, and hence it was neglected and ultimately forgotten by chemists. They were, however, being driven back to it in spite of themselves; and it in no sense detracts from his merit to affirm that even if Cannizzaro had not perceived the truth, the rapidly accumulating mass of evidence would have forced others to recognise it. Indeed the substantial unanimity with which Cannizzaro's doctrine was received, immediately that it became generally known, is a proof that the time was ready for it. It is not too much to say that its effect on the minds of chemical thinkers was as profound as that described by Cannizzaro himself in the memorable lecture before alluded to, when he reminded us of Thomas Thomson's account of the impression produced upon him by Dalton's own verbal explanation of the atomic theory. To paraphrase his words: they were enchanted with the new light which burst upon their minds, and saw at a glance the immense importance of such a theory.

Hence then, when Cannizzaro visited this country in 1872, to deliver the Faraday Lecture to the Fellows of the Chemical Society, of which he has been a Foreign Member since 1862, he spoke to willing and receptive ears, and to a body of men to whom his doctrine was already an established article of their chemical creed.

Cannizzaro is a Foreign Member of many learned Societies; nearly every Academy in Europe, indeed, has delighted to honour him. In 1889 he was elected a Foreign Member of our Royal Society, and two years later he was awarded the Copley Medal for his services to chemical theory. May he long be spared to wear the many honours he has so worthily earned, and to enjoy, in health and increasing prosperity, the respect and esteem of a multitude of friends in both hemispheres!

T. E. THORPE.

EXPERIMENTAL RESEARCHES ON THE PHYSIOLOGY OF REPRODUCTION.

Die Bedingungen der Fortpflanzung bei einigen Algen u. Pilzen. Von Dr. Georg Klebs, Professor in Basel. Mit 3 Tafeln u. 15 Text-figuren. (Jena: Gustav Fischer, 1896.)

IT has long been recognised that in the life cycle of a large number of plants and also of some animals two very distinct modes of reproduction, the sexual and the asexual, recur in a rhythmical fashion.

This fact, crystallised by Steenstrup in his famous doctrine of alternation of generations, has ranked as one of cardinal importance in the treatment of the higher groups of plants ever since Hofmeister showed that the sequence of events in their several life-histories was essentially identical with that obtaining in a moss or in a fern. True it is that in respect of algæ and fungi there existed an uncomfortable *arrière pensée* that all was not quite right, and indeed certain facts seem to be definitely opposed to the general extension of the doctrine to the various members of these classes. Curiously enough it seems not at once to have been clearly apprehended that one has hardly any right to expect to find alternation recurring regularly in these primitive forms; for the very characters which we regard as indicative of primitiveness consist exactly in those negative conditions implied in an, as yet, undeveloped state of division of labour. But it is obvious that, before alternation could possibly have become part of the regular physiological (and

morphological) peculiarities of the race, a good deal of initial specialisation must first have occurred; this will be equally true, whatever view we choose to adopt as to the homologous or antithetic nature of the origin of the process itself.

In the highest forms, we are very far from being able to answer the initial question as to what it is which causes the organism to enter on the reproductive as opposed to the vegetative phase, although as regards the actual phenomena of reproduction itself, we can fairly accurately predict the course which the process will take. But this is merely because it is far less directly affected by the action of the environment than are the functions of nutrition and growth. Nevertheless, although the empirical facts may be easier to glean, their very invariability opposes perhaps the strongest obstacle to our grasping the nature of the chain of causes of which they themselves merely constitute the terminal expression.

But in the lower forms, including most algæ and fungi, the physiological differentiation has not progressed far enough to effect such an adjusted state of organisation as will commonly respond in an identical manner to the action of any stimulus whatever that may happen to be able to excite it at all, for they will either grow vegetatively, or they will reproduce themselves sexually or asexually, according as the exigencies of the environment may demand. It is to them, therefore, that we look to find the clue that shall enable us to penetrate the dense obscurity which at present veils the whole subject.

But although reproduction and the conditions which affect it has long afforded a favourite theme for speculation, its investigation from a scientific and experimental standpoint has been surprisingly neglected. A certain amount of scattered knowledge has been gathered, owing largely to the efforts of gardeners and others practically interested in the solutions of the problems with which we are here concerned, but for definite attempts at thorough investigation by means of inquiries properly formulated and vigorously pursued we have looked, until lately, almost in vain.

Prof. Klebs, then, is the more deserving of the congratulations of all who are interested in these difficult problems on account of the admirable manner in which he has conceived and conducted his elaborate and beautiful series of experiments which are described in the volume before us. For his results conclusively prove that these recondite functions of protoplasm are as amenable to experimental treatment, if approached in a suitable manner, as are those of irritability or of nutrition. It is difficult at present to estimate the exact limitation of Dr. Klebs' methods or the general value of his conclusions, but the results as yet obtained are truly surprising. Instead of uncertainty, we find definite reactions on the part of the organism to varied external conditions, and the present writer can testify to the accuracy of the author's statements in a number of crucial instances.

Of course it is impossible here to give more than a mere sketch of the enormous mass of detailed observation piled up, in a rather unwieldy fashion it must be confessed, in Prof. Klebs' book, but a few typical facts will serve to indicate the general drift both of his methods and his results.

A somewhat large proportion of the entire number of pages is devoted to an account of *Vaucheria terrestris*, of which the author recognises three varieties which showed differences, sometimes slight, sometimes rather striking in the respective manner in which they responded to similar stimuli, but for the details the original treatise may be consulted. The plants were investigated with a view of determining the conditions which govern the formation of the non-sexual zoospores and the sexual gametes respectively, and especial attention was directed to the influence of heat, light, medium of cultivation, organic or inorganic food, and so forth. Dealing with the alga at first from the point of view of its zoospore-formation, a large number of striking facts was elicited. It must be premised that *Vaucheria* only forms zoospores when it is growing immersed in water; but, as will be seen, this is only a very small part of the story, since the conditions to which it happens to have been previously exposed when growing in terrestrial stations have an important influence in determining whether, on immersion, these bodies shall or shall not be produced. For example, if plants which have been grown on soil in a damp atmosphere be suddenly submerged in water, zoospores are copiously produced within a short time, and this is especially the case if the submergence be accompanied by a darkening of the culture, whereas if a *dry* earth culture be similarly treated zoospores may perhaps not be produced at all. They are, in any case, only formed in the upright filaments, such as may be seen rising up abundantly in any specimens cultivated in damp air. Furthermore, the change from an aërial to an aquatic medium must be a sudden one. A gradual submergence produces no effect, and this fact gives us a probable clue to the cause of the failure of plants which have previously been kept dry to form zoospores after immersion. Under these circumstances the erect filaments are not produced, and by the time they do appear in the water culture, the stimulating effect of the change of medium seems to have ceased to operate.

As regards the action of changes of temperature, it was found that in general a rise of a few degrees provoked the formation of the zoospores, especially when the plants were grown at low temperatures, but that the converse process of cooling was without effect. The interesting discovery was made, that whereas the lowest normal limit at which the plants could thrive and retain their sensitivity was about 3° C., this could be considerably lowered by gradually accustoming the plants to increased cold, and that under these circumstances they still responded to an increase of warmth in the usual manner, *i.e.* by the production of a crop of zoospores.

Much interesting matter is to be found in the pages devoted to the consideration of other conditions affecting the production of zoospores; but in this place we will content ourselves with indicating some of the more important ones connected with the influence of light. In water-cultures grown under healthy conditions, zoospores are readily produced on the withdrawal or diminution of light. It turns out that plants exposed to blue light behave as in the dark, *i.e.* they form zoospores, but that in yellow rays these bodies are not produced. It might seem natural, at first sight, to connect this peculiarity in some way with the assimilatory functions which are

discharged in yellow light; but Klebs decides against this, urging that plants grown in air freed from carbon dioxide behave in the same manner. He does not believe that the small amount of assimilation, which can occur by means of the carbon dioxide set free during respiration, can account for the process. Still, it must be admitted that this is an objection which is not devoid of some weight; and the fact that plants grown in certain mineral solutions *only* form zoospores *during light*, seems to indicate that nutrition may yet be found to lie indirectly at the bottom of the matter. At any rate, a good deal more analysis of the conditions is here necessary before we can safely formulate any theory. Klebs himself goes on to speak of the darkness itself as constituting a *reiz* or stimulus; but it is not very easy to see how a negative condition can be quite appropriately so construed. May not the light, or at least the yellow constituent rays, be regarded as exerting a tonic or inhibitory effect, which must first be withdrawn before the already existing tendency can manifest itself in action? It is clear that the same objection might be urged in the case of some other so-called stimuli; but it seems very desirable to avoid any ambiguity of expression, especially in a subject already so difficult, such as is involved in the use of the word stimulus (*reiz*), both for an active promoting cause and for the removal of a restraining influence.

It is extremely instructive to contrast the conditions which excite the formation, in *Vaucheria*, of sexual or asexual reproductive organs respectively. Whereas darkness is advantageous in the case of the latter, the sexual organs are only produced in the presence of fairly strong light, which further must contain just those less refrangible (yellow) rays which inhibit the production of zoospores. The action of the light is here two-fold. Firstly it operates by promoting assimilation, and in this capacity it can largely be dispensed with, provided suitable carbohydrate food be supplied to the plant. Secondly it acts as a direct stimulus, which initiates the formation of the sexual organs, and in this capacity it cannot be replaced. But when once the stimulus has effected the inception of the sexual organs, they may continue to develop in greatly reduced light, the degree of maturity to which they finally attain being largely determined by the initial duration of the stimulus. In *Vaucheria* the oogonia require a stronger excitation than that sufficing to produce the antheridia; and consequently it is possible, by regulating the illumination, to raise plants bearing only male organs.

Similarly, Klebs determined the corresponding special conditions in the case of a considerable number of other algæ. Several of these are of particular interest as illustrating the individual vagaries and idiosyncrasies of the different species, and also as forcibly emphasising the danger of drawing general conclusions rom an insufficiently wide area of facts. For example, *Hydrodictyon* can be induced, as a general rule, to readily reproduce sexually or asexually at the will of the experimenter; but it occasionally happens, as the consequence of certain modes of cultivation, that it develops a very pronounced tendency to form zoospores only, and under these circumstances all the ordinary methods which are commonly efficacious in producing gametes are futile. The plant must first be broken of its tendency to form zoospores; and this can be done by keeping it at a high temperature, and in the dark. This inclination to a particular form of reproduction is of some significance when taken in connection with the difficulty, which is often experienced in many fungi, of securing any but the non-sexual form of reproduction; but it is of still wider interest as once more illustrating the fact that, although external stimuli may evoke this or that form of response, the actual form of the response itself is, after all, not so much determined by the nature of the stimulus as by the particular condition of the special protoplasmic mechanism through which it operates.

Another example may be quoted as illustrating the difficulty of drawing any general conclusion from Klebs' experiments at present. This is not meant by way of disparagement, for his results are in the highest degree useful as affording numerous exact data, even though they hold, it may be, only for isolated individual species. Thus two species of *Œdogonium* were investigated, namely, *Œd. diplandrum* and *Œd. capillare.* Both of these were found growing in the water, often side by side; and yet in hardly a single respect does the stimulus, adequate to provoke the formation of zoospores in the one species, produce a similar effect on the other. The chief differences may be shortly summarised as follows.

(1) In *Œd. diplandrum* a rise of temperature is one of the most effective means (provided too great heat be avoided), whereas in the case of *Œd. capillare* it produces absolutely no effect whatever.

(2) In *Œd. diplandrum* a transference from running to still water produces zoospores, whether in light or darkness; the diminution of oxygen apparently providing the real stimulus here. In *Œd. capillare*, on the other hand, the reaction only occurs in the darkness; the latter condition being, in this case, essential to success.

(3) In *Œd. diplandrum* light is absolutely without influence on the process, whilst in *Œd. capillare* it possesses a powerfully inhibitive action. That mere darkening is not the proximate cause of the zoospore formation, is proved by the fact that the process only begins after a prolonged stay (two days) in the dark; that is, probably, the withdrawal of light allows some change to proceed within the protoplasm, and that the effect of this is to act ultimately as a stimulus to the formation of the swarm-cells.

If anything were needed to show how important is the nature of the protoplasm in each individual instance when considering the result which may follow on identical external stimuli, it would be hard to conceive of a better example than that afforded by the behaviour of these two species of *Œdogonium.* What the nature of the internal mechanism may be, or how the stimuli actually affect it, is absolutely obscure—as obscure, indeed, as are the reactions of the plant to gravity or to the directive influence of light—so soon as we seek to penetrate beyond the region of mere empirical fact. In the case before us Klebs suggests that plasmolysis, and other disturbances of the normal relations of the salts dissolved in the cell-sap, may be the determining factor, but his arguments are not very convincing, and, indeed, such an hypothesis recalls the rough and ready "explanations" which used to be put forward as solving the riddles of heliotropism and the like; but

quite apart from this, some of his own direct observations appear to tell strongly against it.

The development of the *sexual* organs in these lower plants is much less variably affected by the influence of the surrounding conditions (a very significant fact, even in these primitive forms) than is that of the non-sexual ones. Light, in greater or less intensity, is commonly essential, and, as has been said in connection with *Vaucheria*, it acts both directly as an initiating stimulus, and indirectly as affecting the function of assimilation. Again, cultivation in a small amount of water, together with the absence or at least scarcity of inorganic nutrient salts, encourages their formation; whilst the addition of the last-named salts commonly suffices at once to check the process, and frequently causes the resumption of vegetative activity.

The case of Spirogyra is of some special interest in this connection, owing to the remarkable disturbances which the addition of appropriate salts may effect in cultures in which conjugation is freely proceeding. These disturbances may take the form, in weak organic salt solutions, of partial arrest of conjugation, the gametes then clothing themselves with a wall while still within their own mother-cells, and finally growing vegetatively as any ordinary separated cell of a filament would do. If, however, the solution be sufficiently concentrated, the gametes develop to form parthenospores indistinguishable, when mature, from true zygospores. Similar effects can be brought about by sugar solutions of appropriate strength. It is important, however, to notice that it is only at certain stages in the development of the gametes that their further development can be arrested, and parthenospore-formation be induced; and this, taken together with the varied behaviour exhibited by the different species, emphasises what has already been said as to the need of taking due account of the "personal equation" of the individual in all inquiries of this kind.

A number of valuable observations on fungi are also recorded in the book; but space forbids further mention of them here, beyond the one fact, which may prove of practical use to teachers, namely, that bread-cultures of *Eurotium* can be made to produce archicarps, &c., with certainty in about two days, if kept at a temperature of 28°—29° C.

Prof. Klebs, whilst mainly concerned with the problems of the physiology of reproduction, incidentally touches on several points of taxonomic interest, and, in particular, he clears up the difficulties which have often been felt with regard to *Botrydium*, by showing that two distinct organisms have been confounded under this name. He proposes to separate them into two genera, retaining one of them in the old genus *Botrydium*, and creating a new one—*Protosiphon*—to include the other.

It is quite impossible within comparatively moderate limits of space to do justice to the great wealth of observation and experiment recorded in the volume before us; the work is essentially one which everybody who is interested in the subject ought to study for himself; and if he finds it rather a bewildering treatise, he will, nevertheless, be amply repaid for his trouble, and may further take comfort from the fact that the author promises another volume in which the points of theoretical interest will be brought more nearly together, and their general bearings discussed. J. B. F.

SHAKESPEARIAN NATURAL HISTORY.

Natural History in Shakespeare's Time: being Extracts illustrative of the Subject as he knew it. By H. W. Seager. 8vo, pp. viii + 358. Illustrated. (London: Elliot Stock, 1896.)

WHETHER, as a student, absorbed in the dry details of systematic work, or whether, as a spectator, interested in the marvellous displays of our museums, we of the present day are too apt to forget that natural history has lost one of the greatest of all charms—the charm of the unknown and the mysterious. To us a new animal merely fills one more gap—it may be large or it may be small—in the chain of nature; its interest, unless it be of striking form and beauty, or have something out of the common in its structure, being generally confined to the specialist. Not so the naturalist (save the mark!) of Shakespeare's day. To him the voyager, on his return to his native land, brought some new legend of the cockatrice, the mermaid, the phœnix, or the unicorn, or told of creatures the like of which had never before been heard of in heaven or earth. It mattered not that *spolia opima*, in the shape of talons, skins, eggs, or feathers, were not to the fore to confirm the story; there the story was, and that sufficed.

Now that the cold light of science has thrown its ray upon the most remote parts of our globe, there is no longer room for legendary creatures—save the sea-serpent; and we are told that the mermaid is nothing more than a dugong, a unicorn either a rhinoceros or a Tibetan antelope, while the cockatrice, the phœnix, and the roc appear to be pure imaginations.

But in the Elizabethan age—an age when the dodo had but recently been discovered—these, and many other mythical creatures, were, if not living, at all events actual realities to the ordinary public, and as such were referred to in the works of the great dramatist and other contemporary writers. We meet, for instance, in the *Winter's Tale* the line, "Make me not sighted like the basilisk," and in the *Tempest*, "Now I will believe that there are unicorns." But not only was more or less of credulity given to the existence of these and such-like fabulous monsters, but a web of mystic lore encircled the most common and best known of beasts, birds, and fishes. Who, for instance, is forgetful of the popular superstitions connected with the salamander, the newt, and the blindworm, and who fails to remember White's account of the "shrew-ash" at Selborne? And if such superstitions still survive among uneducated peasants of the present day, we may be assured that two centuries ago they were fully believed by the higher classes.

As the author states in his preface, the work before us "presents in a convenient form for reference a collection of the quaint theories about Natural History accepted by Shakespeare and his contemporaries. . . . The plan of the book is to give some illustration of each word mentioned by Shakespeare when there is anything remarkable to be noted about it." It is added that the term Natural History is taken to include not only plants as well as animals, but likewise some precious stones. It is further stated, that although Shakespeare had a greater knowledge of natural history than many of his contemporaries, yet that even he gave credence to many

of the legends he quotes, especially in regard to the animals and plants of distant lands.

The early writers whom the author quotes as his authorities form a long list of names. Among them are Friar Bartholomew and his editor Batman, whose works seem to have been the standard natural history of Shakespeare's boyhood; Topsell, so beloved of the late J. G. Wood; Gerard and Parkinson, as known by their respective *Herbals*; Holland, in his translation of Pliny's Natural History; and Evelyn, of *Silva* fame. Long quotations from these and other writers are given under the heading of the more important animals, plants, and jewels; contemporary illustrations being in many instances reproduced.

Many of these latter are of the quaintest, and form puzzles for the naturalist to discover the animals from which they were compounded. The crocodile, for example, is represented as a very marvellous complex animal, having a head which can scarcely have been taken from aught else but a wild boar, while in the armature of its back and fore limbs it recalls a pangolin; and the panther (p. 131) is more like a spotted hyæna than the creature it is intended to portray. What can have been the origin of the eight-rayed crest on the head of the serpent (p. 280), it is hard indeed to guess. But the most marvellous creature of all is the reputed whale (p. 341), which is a pig-faced, four-legged, scaly animal, with a long tail ending in flukes; the creature being represented as having just climbed on the poop of a vessel, with its head high up among the rigging. It has surely much more connection with certain modern stories of the sea-serpent than with any whale that ever swam.

That the author has succeeded in producing a very delightful and, to a certain extent, an instructive volume, may be freely granted. At the same time, it would have been decidedly an improvement had he given some explanation of the legends connected with real animals and plants, and likewise have offered suggestions as to the origin of mythical ones. As it is, the reader is left almost or completely in the dark on both these points. It is not as if nothing had been written in modern times upon such subjects. For instance, we find on p. 11 the following sentence: "And it is said that in Ethiopia be Ants shap [ed] as hornets, and diggeth up golden gravel with their feet, and keep it that it be not taken away." Now if the author had consulted a paper by the late Dr. Valentine Ball, published some years ago, we believe, in the *Proceedings of the Royal Irish Academy*, he would have found some interesting information concerning these gold-digging ants, and also about many legends connected with other animals, both real and fabulous. Again, when treating of sirens, or mermaids, the non-scientific reader would probably like to have been informed that the legend almost certainly originated from dugongs having been mistaken for sea-maidens. All that the early writers have said of the unicorn is very fully given, but a few words as to what modern authorities think as to the origin of the myth would surely have been acceptable. As it stands, we can, however, confidently recommend the work to all who are interested in learning what were the views of our non-scientific ancestors of two centuries ago as to the habits and uses of animals and plants of their own and foreign lands.

R. L.

OUR BOOK SHELF.

Chapters on the Aims and Practice of Teaching. Edited by Prof. Frederic Spencer, M.A., Ph.D. Pp. viii + 284. (Cambridge: University Press, 1897.)

THIS book should be read by all who are interested in educational methods. With the chapters on the teaching of Greek, Latin, French, German, English and History, we are not much concerned; our only regret is that the methods of teaching languages described therein were not in use in our own schooldays.

As to the chapters on the teaching of various branches of science, we commend them to every earnest teacher. Geography is dealt with by Mr. H. Yule Oldham, who, beginning with the consideration of position, distance and area, as exemplified in the schoolground and parish, passes therefrom to the consideration of the British Isles and the earth as a whole. The plan of study he sketches makes geography a living science, instead of a demoralising exercise for the memory. Prof. G. B. Mathews plans an algebra course, and urges that the natural approach to the study of it is by the way of ordinary arithmetic. After simple arithmetical algebra come rules of sign, negative quantities, factors, geometrical progression, and then surds. The way to teach geometry is shown by Mr. W. P. Workman, whose many suggestive and practical hints will, perhaps, help teachers to see that the main function of the subject is intellectual discipline.

Methods of teaching physical science are described by Dr. R. W. Stewart. The method of teaching advocated involves theory, demonstrations, and individual laboratory work, but the research attitude of the learner is not advised; for, says Dr. Stewart, "Experimental work is of no value whatever unless the theoretical knowledge of the scholar is full enough to enable him to understand clearly the objects and the details of the experiment." Against this view we have Dr. H. E. Armstrong's remark, in his very helpful chapter on the teaching of chemistry, that "students are not to be *told* about things, or even to be *shown* things, but are to be trained to *solve problems* by experiment—that is to say, they are to be trained to *discover*; and their discoveries are to have reference to common objects and phenomena." Two brief chapters on the teaching of botany and physiology, by Prof. R. W. Phillips and Dr. Alexander Hill respectively, conclude the volume.

Education in this country will certainly gain by the publication of these chapters on pedagogic methods.

Star Atlas. By W. Upton. Pp. iv + 29, and plates. (London, and Boston, U.S.A.: Ginn and Co., 1896.)

THIS atlas is primarily intended as an educational guide for the amateur astronomer; and with this end in view, no stars fainter than the sixth magnitude have been charted, thus avoiding the crowding in of detail inseparable from more complete star atlases.

Stereographic projection is adopted throughout the series of six maps, two of which are circumpolar, showing northern and southern stars; the remaining four cover the regions lying between N. 40° and S. 40° declination.

In addition there are six key maps, plotted to half the scale of the principal series, showing only the chief stars, and having connecting lines drawn between the stars of each constellation. These will be found useful in passing from one constellation to another when searching for an object.

The explanatory text gives a brief outline of the history of the formation of constellation-areas, the names and designations of the stars, and the system of indicating magnitudes. Very representative and concise catalogues of double stars and nebulæ are given, and following these are lists of variable and coloured stars. The lettering and outlining of the groups is very legible; but it still seems usual for the ancient constellation figures to mask somewhat the resemblance of a star chart to the sky as

seen by the eye. It would be better if these were put in as finely as possible, if included at all. The atlas is well up-to-date; and, owing to this fact, will probably be useful to the professional as well as to the amateur. The star places are marked for the epoch 1900, and the Harvard photometry has been taken as the authority for the magnitudes, the positions being derived chiefly from Argelander's Uranometria Nova. For observers possessed of instruments of moderate size, this atlas will probably prove a useful companion.

A Protest against the Modern Development of Unmusical Tone. By Thomas C. Lewis. Pp. 46. (London: Chiswick Press, 1897.)

THE prevalent practice in organ-building of the present day is to use for the middle C a pipe too large in scale, and with mouths cut too high, the result being, according to the author, that the Diapason tone, which rules every other stop in an organ, has deteriorated in quality. A pipe which will give an ideal Diapason tone is specified, and the defects in organs which do not conform to the conditions laid down are criticised. The protest as regards church bells is chiefly directed against excessive thickness. In pianofortes the destruction of pure tone is held to be due "to an increase of heaviness in the hammers for the pounding of the strings, to an excess of rigidity in the framework and setting, counteracting the vibrating motion of the strings—to an excess of scale in the length of strings—to the production of false harmonics, and the absence of due proportion between the ground-tone and the harmonics, and generally to the making of more noise than music in the quality heard." The brochure contains some interesting information on the principles of the construction of organ-pipes, bells, and pianofortes.

Respiratory Proteids, Researches in Biological Chemistry. By A. B. Griffiths, Ph.D. Pp. v + 126. (London: L. Reeve and Co., 1897.)

THE conclusion which the author of this book aims at establishing is that there are several respiratory proteids (both coloured and colourless) in the blood of animals. The introductory chapter, occupying one-third of the pages of the book, brings together some interesting information on the constitution of the blood of echinoderms, annelids, insects, arachnids, crustaceans, molluscs and vertebrates. Following this are chapters on various respiratory pigments found in the blood of certain animals, and on colourless respiratory proteids. Chapters on the nature and functions of chlorophyll and hæmoglobin conclude the text. An appendix is devoted to brief descriptions of the chemical compositions of the chief pigments which occur in the bodies of animals, and the methods by which they may be extracted.

The book should be serviceable in directing attention to the comparatively neglected field of biological chemistry, even if all the views it contains as to biochemical processes are not accepted.

Outlines of Psychology. By Wilhelm Wundt. Translated by C. H. Judd. Pp. xviii + 342. (Leipzig: Wm. Engelmann. London: Williams and Norgate, 1897.)

THIS book differs from the other works of Prof. Wundt in being more purely psychological, the physiological aspect of the subject being kept as much as possible in the background. Like the other works, it is an exposition of the special attitude of the author rather than a critical account of the present state of knowledge on the subject; but this is a feature common to most psychological text-books. For those who wish to learn the views held by the leader of one of the chief schools of modern psychology, the present volume will serve excellently. The translation is good, and Dr. Judd has added a useful glossary giving the German equivalents of the chief psychological terms used.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Organised or Sectional Work in Astronomy.

THE remark was recently made by Prof. S. C. Chandler that, notwithstanding there had been no recent systematic arrangement of work in connection with variable stars, the result was most gratifying; for the observations were fairly complete, few interesting objects having been neglected. He says that "this satisfactory result could hardly have been reached so effectively by a formal organisation of work directed from headquarters, prescribing and circumscribing the operations of each participant, and destroying by its benumbing influence the enthusiasm which springs from the individual initiative of the observers themselves."

This statement emanating, as it does, from a thoroughly practical man, and being based on unequivocal facts, must commend itself to the consideration of every one interested or engaged in the sectional work of various societies. It is evidently a point worth inquiry, as to whether Prof. Chandler's remark applies with equal force to other departments of astronomy besides that of variable stars. Having had some little experience in the sectional work of the Liverpool and other astronomical associations, I may perhaps be allowed to express the opinion that, while in some branches there is great utility in co-operation, in others the material advantage is rather questionable. In comet-seeking the division of labour seems eminently desirable, because one observer cannot possibly examine all the available sky at sufficiently short intervals. In meteoric researches, also, concerted effort is most valuable for the purpose of securing duplicate observations. Amateurs, by pre-arranging the hours for simultaneously watching the heavens, and the particular region for each one to observe, are enabled to secure a number of observations of identical objects, and the real paths of these may be derived from the materials gathered in this way. If left to independent effort, the chances of success would be greatly diminished, and the accuracy of the observations impaired; for a person when engaged in special combined work is apt to put forth his best energies, and the appearance of a large meteor is not likely to find him unprepared, unless it comes at a time not included in the prescribed hours of work.

But, in some other departments of observation, there does not appear to exist the same necessity for organised effort. In fact, I think that it can be shown from results—the best of all tests—that it has been a comparative failure as far as it affects the progress of astronomy. Of course a great deal depends upon the director of a section. If he is a man of great resource and skill, he will be pretty sure to have something tangible to show for his work, and that of his colleagues. The worst of it is that, in publishing collective results, the good, bad, and indifferent are indiscriminately presented; and there being, perhaps, no criterion by which to distinguish them, the whole are virtually rendered useless. Taking any band of unselected observers those of moderate or poor capacity will greatly predominate. Even in meteoric astronomy, I would not, for an instant, recommend that the results of several observers should be combined with the idea of accurately determining the positions of radiant points. In such cases the bad or moderate observations swamp the trustworthy ones, and we can get radiants anywhere or nowhere, just as we like to interpret the evidence afforded by the materials before us. It is a most important requirement that really precise observations should be preserved from contact or collaboration with others of inferior character.

A little reflection will prove that all the best work has been accomplished by individual and independent effort. A good man will persevere in his labours, just the same, whether he belongs to any combination or not; and it is really much better for such a person to be isolated, so that he may perform the work of his choice in his own way, and publish it in his own style. If a man has the ability to accomplish useful work, he will know the best form in which it may be presented for the benefit of science. Moreover, he needs no encouragement; he proceeds with his research because he is actuated by the love of it, and sees the beacon of success shining invitingly in the foreground.

Undoubtedly, cases could be cited where combined work has been or will be most efficacious. In an object of exceptional

kind, like that involved in the preparation of the photographic chart of the heavens, it was absolutely necessary, from the magnitude of the undertaking, that a collective effort should be made. In another case, that of the British Association Committee on Luminous Meteors, which existed between 1848 and 1881, a mass of valuable work was performed (as the annual reports will testify) by the collection and discussion of observations and investigation of theories. Other instances might be adduced, but they are rather exceptional in character and distinct to the ordinary sectional work of societies.

In certain respects, it cannot be denied that the latter serve a useful purpose. Many gentlemen find it an encouragement and a source of interest to engage with others in combined work. They are thus enabled to compare notes, and it is a satisfaction to feel that a bond of association exists between them, and that they are all actively employed in a similar direction. Observations are taken, drawings are made, and many hours are spent at the telescope, which would never be so employed but for the influence of the circumstances referred to. They have the pleasure of seeing their observations in print; possibly some of their drawings are also reproduced, and the consciousness of having done something to merit public notice cannot fail to stimulate them to further effort. But, in such cases, it must be admitted that the benefit to science is inconsiderable. Very little work of real value is accomplished in this way, and in many instances the observations are not properly reduced and utilised as they should be. It is not sufficient that results of this kind should be simply allowed, year after year, to accumulate. Many thousands of drawings and observations have been made by the members of planetary sections; but we can trace very few salient facts, or additions to our knowledge, as the outcome of them all. Observers, as a rule, do not probe into their subject with sufficient depth, and ferret out all the details possible of any particular object observed. Nor is attention always directed to those points which are the most significant and suggestive. It needs a man like Mr. Marth to be the really efficient director of a section, to single out the really essential work to be performed, and then to sift it with thoroughness and critical accuracy.

To beginners sectional work is often most beneficial, as it affords them a useful preliminary training. But observers who need and will submit to "direction," except at the outset of their careers, are not generally the men who accomplish work of an important and enduring kind. The aspirations of a really capable man are not likely to be satisfied by the facilities offered by combination with many others. It has been said, "Talent does what it can, Genius does what it must." When a young observer begins to feel confidence in himself, it is, perhaps, better that he should strike out in a path of his own. There are some who will naturally be allured by the prospects of doing original work, and effecting discoveries in an independent way. They do not want to triple the channels of Mars, to distinguish the hard straight lines on Mercury and Venus, or to trace the zebra-leopard-like aspect of the globe of Saturn. But they want to do really useful work, and to rely only upon the unmistakable evidence of their eyes; in this respect, dissociating themselves from some modern observers, who can but very vaguely discriminate between romance and reality.

To sum up the matter: it appears that the organised work of "sections," though it unquestionably affords a stimulus to many, and assists in maintaining the interest in a subject, is yet. except in certain special circumstances and cases, disappointing and unproductive of results which materially advance astronomy. Individual and independent effort has hitherto been, and will still continue to be, the fountain-head of the most valuable work.

In concluding, it may be mentioned that the issues of recent planetary observation appear to be totally dissimilar to anything previously experienced in astronomical history. No two observers see alike when they examine the images of Mercury, Venus, Mars, or Saturn, and the actual character of the visible surface markings of these orbs is more an enigma than it was in the days of Herschel and Schroeter. There is also a pronounced conflict of opinion as to the utility of large and small telescopes in displaying delicate features on the planets. This want of unanimity amongst observers has become a serious question to consider; in its presence organised attempts to study the planets are of little avail, since many individuals seem to display their own particular idiosyncrasies and peccadilloes, greatly to the chagrin of every director of a section, who finds his post no sinecure.

W. F. DENNING.

Shelly Glacial Deposits.

I FEAR that the hope expressed by Prof. Bonney, somewhat incongruously in its connection, in his recent review of Russell's "Glaciers of North America," that "perhaps in future we shall hear less of rampant ice-sheets at Gloppa and Moel Tryfan!" is not destined to be fulfilled. There will be something more to hear shortly, if he care to listen, respecting that part of this ice-sheet which covered the Isle of Man. This portion was distinctly of the "rampant" type, as Mr. P. F. Kendall has already shown, carrying up shells in one place, and boulders of Foxdale granite in another, and erratics from the south of Scotland in another, as a matter of every-day work—just as recent investigations have shown to be the case in regions where to-day there are glaciers of other than the Alpine type.

I am quite in agreement with Prof. Bonney when, elsewhere in his review, he asks: "May not the difficulties of the subject be augmented by defective knowledge?" For this reason I may be pardoned for once more dragging forward the facts which I put on record some years ago respecting the shelly Basement Clay of the Yorkshire Coast. In this deposit the shells occur not only scattered throughout the clay, but also in limited patches or boulders of marine sand and mud, which are associated with similar masses of peat and mud of fresh-water origin, and with patches of shale and clay derived from the Lower Cretaceous and Jurassic strata of the country farther northward with the bedding still preserved and the characteristic fossils in place.

These facts have never been impugned, but they are rarely referred to by the opponents of the "rampant ice-sheets." They have surely a more immediate and direct bearing upon the subject than the isolated observation respecting the deposit in the neighbourhood of the Malaspina Glacier on which Prof. Bonney leans so wide a hope.

If the sands and gravels accompanying this Yorkshire drift-series be, as is usually held, the result of the washing-out of the same material, the shelly fragments contained therein are no better proof that the gravels are of marine origin than their derivative Jurassic fossils are that they are of Jurassic age.

I do not think that any one has attempted to deny that marine deposits of Glacial age may and do exist within the limits of the British Islands. But what the "extreme glacialists" wish to insist upon is that better evidence is required than the mere presence of sporadic marine organisms to prove such origin against the very strong evidence which can be adduced against it in such instances as those referred to by Prof. Bonney.

Dalby, Isle of Man, April 22. G. W. LAMPLUGH.

Sieve for Primes.

MAY I draw the attention of your readers to a series from which the primes may be recovered?

The series is given below, together with the accompanying primes.

1,	4,	11,	29,	76,	199,	521,	1364,	3571,	9349,	&c.
1.	3.	5.	7.		11.	13.		17.	19,	&c.
		2.								

The law of formation is $a_{n+1} \equiv 3a_n - a_{n-1}$.

It can be proved in various ways that the nth term of

$$(w_2 + w_3)^{2n-1} + (w_4 \div w_5)^{2n-1} - 1 \equiv p.q$$

where the roots are the unreal of $x^5 + 1 \equiv 0$ and $p = 2n - 1$ is any odd prime.

Is 13 a prime? Yes; because the 7th term ($2 \times 7 - 1 = 13$) minus unity $= 13\,q$.

Is 15 a prime? No; because the 8th term less unity is not $= 15\,q$.

These are but easy numbers to test; but the law is general.

We have here an alternative test for primes.

The series given above is intimately connected with the well-known "continuant" series 1, 1, 2, 3, 5, 8, 13, &c., whose law of formation is obvious.

The connection between the two series is as follows:—

Let a, b, be any two consecutive terms of the "continuant" series.

Then $5\,ab \pm 1$ will give the corresponding term in the former series.

There are other series which produce the primes, but the above can be produced *mechanically*.

I append a short proof, out of several which may be given. We have to show that

$$(w_2 + w_3)^{2n-1} + (w_4 + w_5)^{2n-1} \equiv 1 \bmod 2n - 1$$

when, and when only $2n - 1$ is prime.

Let w_2, w_3, w_4, w_5 be the unreal roots of $x^5 + 1 \equiv 0$ and $2n - 1 =$ any odd prime, then we may say

$$\left(\frac{1+\sqrt{5}}{2}\right)^p + \left(\frac{1-\sqrt{5}}{2}\right) = 1 \bmod p$$

$$= \left\{\frac{1 + pk + (\sqrt{5})^p}{2^p}\right\} + \left\{\frac{1 - pl - (\sqrt{5})^p}{2^p}\right\} = 1 \bmod p \text{ where } p$$

is any *odd* prime.

$$= \frac{2 + 2\,p.m}{2^p} = 1 \bmod p \text{ or } \frac{1 + p.m}{2^{p-1}} = 1 \bmod p.$$

Now, by Fermat's theorem $2^{p-1} - 1 = p.n$ when, and when only p is prime. Thus

$$p.m - p.n = 0 \bmod p$$

which proves the theorem for any *odd* prime.

It is also true for $p = 2$, since by ordinary work

$$\frac{1 + 2\sqrt{5} + 5}{4} + \frac{1 - 2\sqrt{5} + 5}{4} = 3 = 1 \bmod 2.$$

Thus the theorem is universally true for all primes.

It is remarkable that the second factor of the prime series given above is also a function of the prime p, viz.:

$$1 + \frac{p-3}{2!} + \frac{p-4 \cdot p-5}{3!} + \frac{p-5 \cdot p-6 \quad p-7}{4!} +, \text{\&c.}$$

ex. gr. the 4th term of the prime series is 29, thus

$$29 - 1 = 7\left\{1 + \frac{7-3}{2!} + \frac{7-4 \cdot 7-5 \cdot}{3!}\right\} = 7\{1 + 2 + 1\} = 28.$$

As this communication is somewhat long, I reserve the proof of this. ROBT. W. D. CHRISTIE.

April 28.

The Effect of Sunlight on the Tints of Birds' Eggs.

THE beautiful and delicate colours observed on the eggs of birds are not very fast to light, more especially when they belong to the lighter class of colours. Egg-collections should be carefully protected from the light by some covering over the case, when they are not being inspected; otherwise much of their beauty of tint becomes lost in course of time. It is gratifying to notice that in museums and natural history collections this precaution of protecting egg-cases with covers is now almost universally observed. In many instances some of the finest and most characteristic tints of several eggs disappear on exposure to much sunlight. A common example may be found in the beautiful pale blue of the starling's egg (*Sturnus vulgaris*). This, on exposure to sunlight for a few days, loses its clear blueness of tone, and becomes purplier, approaching more to the slate tint. Such is also the case with most of the greenish-blue eggs, like those of many sea-birds, the common guillemot's (*Uria troile*), for instance, the beauty of which largely depends on the clear freshness of its blue tints. The writer, some time ago, made some experiments on the fastness to sunlight of those egg-tints. The method employed was a very simple one, and may be briefly described as follows. Various birds' eggs were selected for experiment, those having decided and well-marked colours being preferred. These shells were halved lengthwise, care being taken before the operation to divide it so that each half should, as nearly as possible, present the same amount of colouring. One half was kept from the light for future comparison, while the other half was exposed in a glass case to direct sunshine. After various exposures, amounting to one hundred hours' sunshine, each exposed half was then compared with its unexposed counterpart, and the changes in hue carefully noted. Little change was visible in the darker coloured eggs of the olive-brown or chocolate depth, but in the lighter tints, especially among the blues and green-blues, the changes became more marked. Among the darker shades of eggs was the common curlew's or whaup (*Numenius arquata*), with its dull olive-green spotted with deep shades of brown; and also the lapwing (*Vanellus cistatus*), which closely resembles in general appearance that of the curlew. Such deeply-coloured eggs are little altered on exposure to light, unless after very long exposure, when they lose some of their rich warmth of tone, and become a trifle clearer in their ground tints, making them look somewhat bleached. Many sea-birds' eggs have a bluish-green colour—sea-green it might be called—which, when new and unexposed, is rich and beautiful. This clear tint, however, is lost on exposure, and it assumes a more dingy slate hue. Some of their eggs have a network of white chalk-like incrustation streaked over the bluish ground tint. This may be seen on the egg of the common cormorant (*Phalacrocorax carbo*). If such shells be exposed for several days to sunlight, and afterwards the white incrustation removed with a knife, the difference produced on the ground tint by exposure becomes at once apparent. The exposed parts will be found of a slaty, duller hue, more approaching a stone-grey tint; while the unexposed parts, protected by the incrustation, will reveal the original sea-green tint in all its freshness. Another example is the fair blue egg of the common thrush or mavis (*Turdus musicus*). This egg when newly laid is of soft light blue of a fine shade, but on exposure it loses much of this clearness of tint, and becomes dull and purply, tending more to a leaden hue. Many similar examples might be given of beautiful shades of blue and blue-green tinted eggs which all tend to become redder and duller on exposure. The red blotched egg of the fieldfare (*Turdus pilaris*) fades in this manner, and the red markings assume a lighter rusty-brown hue. The ring ouzel (*Turdus torquatus*) so well known for its predatory visits to the strawberry-beds, has an egg closely resembling the fieldfare's, both in ground tint and markings, which undergoes the same changes in every respect. One of the commonest eggs is that of the blackbird; it also loses its greenish hue and becomes more of a stone-grey, while its varied markings lose considerably in depth. In the beautiful eggs of the yellow hammer (*Emberiza citrinella*), so curiously veined and mottled with dark red-brown over a pale ground, little or no fading was visible after exposure. Its markings may thus be considered fast to light. There are but few coloured eggs which show no appreciable change after so severe an exposure test as 100 hours' direct sunlight. A good example of a fairly fast-coloured egg is that of the favourite songster the skylark (*Alauda arvensis*). Its eggs vary considerably in colour, but they are always of an indescribable hue, sometimes an ashy brown, or a dark purplish grey, other times more of a greenish tinge. These stand the light very well. The specimens tested looked only a trifle bleached, but those having the greener tinge fade more. One of the prettiest of blue eggs is that of the the common hedge-sparrow. The loss of its clear blue tint to a purplish blue drab was most marked. To illustrate the unstable nature of egg-colouring in comparison with colours of different origin, various other colours resembling in tint those of the eggs were exposed in a similar manner. These were "distemper" colours, and water colours, painted on paper, and coal-tar colours dyed on wool. The distemper colours were perfectly fast to light; their colour constituents all being of mineral origin. The water colours examined were both of mineral and vegetable origin; those belonging to the latter faded very considerably. The coal-tar colours selected were mostly of the bluish cast, corresponding to many of the egg tints. The summary of the results obtained might be tabulated as follows:—

Colours examined.	Result after 100 hours' exposure.
Distemper colours...	100 per cent. fast.
Water colours	60 ,, ,,
Coal-tar colours	30 ,, ,,
Egg-shell colours	20 ,, ,,

The above results, along with the few common examples which have just been given, readily show that eggs lose much of their delicate and characteristic beauty of tint on being too freely exposed to sunlight. DAVID PATERSON.

Rosslyn, Midlothian.

Physiological Specific Characters.

PROF. R. MELDOLA, in his very suggestive presidential address to the Entomological Society, remarks (*Trans.* Ent. Soc. for 1896, Pt. v. p. lxxviii.):—"At any rate, it appears to me inconceivable that any change of environment requiring a modification of structure of sufficient magnitude to rank as diagnostic in the systematic sense, should not also be accompanied by a

greater or less amount of physiological readjustment." But in a foot-note on the very same page, in which he discusses the present writer's statement that specific characters are essentially physiological, he says :—"There must be so much in common in the physiological processes of allied species, that well-marked physiological differences cannot, without further evidence, be regarded as the universal characteristic of specific differences." These two statements are surely somewhat contradictory, and as the proposition I made appears to me to be a fundamental one, I desire to offer some explanatory remarks, especially as few critics will probably trouble themselves to look at the original paper.

I think Prof. Meldola, throughout his address, uses the term "physiological" in too narrow a sense. Morphology, as I understand it, has to do with form, physiology with function. My contention was exactly that of Dr. Wallace, that specific characters have to do with function—are functional, or else coincide with those that are functional. They may be internal or external; an internal process is no more "physiological" than an external one.

But I pointed out, that the very same morphological characters may be specific in one form, varietal in another. The reason why they are specific in the one case is, that they have a physiological as well as morphological significance; they are variable in the other, because they have little or no functional value, although under new environment they may come to have such value, and then through selection become specific.

A dead insect appears equally important in all its parts; function no longer exists, and they are reduced to a common level. But how different is the living creature! Each part now has a special significance; it is a tool, and some tools are more important—more useful—than others. Just in proportion to their value are they elaborated, and kept to one pattern, or, sometimes, to a choice of two or more patterns, as in dimorphic or trimorphic species. Those who claim that specific characters exist without any reason, have got to explain why it is that the very same characters are constant in one form and variable in another; or sometimes even constant in one part of the range of a species, and utterly variable in another part.

Therefore, taking up the first-quoted sentence from Prof. Meldola, I would object that environment never does "require a modification of structure" which has not also a physiological meaning. It is not necessary, of course, that there should be a functional change in *kind*, it must very often be simply a change in *degree*.

In another part of my paper quoted (*Proc.* Phila. Acad., 1896, p. 45) I express more nearly what Prof. Meldola seems to have intended, but I use the term "constitutional," thus:—

"Furthermore, it is apparent that the earliest distinctions between species are at least often of a very subtle character, so that the workings of natural selection during the actual process of segregation are anything but easy to observe. And this need not surprise us when we reflect that among ourselves constitutional characters, not easily identified by any coincident structural features, play so large a part in determining our ability to reach manhood and beget offspring."

It must not be forgotten that in describing a new species, we always include *more* than the actual specific characters, although, as Prof. Meldola excellently points out, we always miss a large proportion of the latter. Generic, subgeneric, and sectional characters are built upon the specific characters of former ages, but they need not now possess a special function. They are, however, the groundwork on which new specific characters are built, and they constitute, in a sense, part of the environment which directs the moulding of those characters. It is when they come too directly in conflict with the external environment that the species becomes extinct. Thus species come to be judged by their ancestors.

A good instance of the correlation of function with structure is afforded by the wings of bees. These insects are classified largely on apparently trivial differences in the venation of the wings. But those who observe them in nature see that with these differences go differences in flight, and it is obvious that there must also exist important differences in the muscles of the thorax, so subtle that at present we know little or nothing about them. Even the psychological characters of these bees must differ. We do not yet know enough about the principles of insect flight to say exactly what influence slight changes in venation would have, but the influence need not be doubted. Recently, I discovered a new genus (*Philereumulus*) of bees with very peculiar venation, and its flight also was peculiar, rapid zigzags just above the surface of the ground, making it impossible to catch it in a net. Many bees can be caught by sweeping; *Centris*, with its hovering pendulum-like swing over the flowers it visits, must be caught by a rapid stroke, or it darts suddenly away.

Prof. Meldola, in his address, has ably shown the need for more subtle observations on the specific characters of insects, and if his suggestive remarks do not stir some of our entomologists up to new ways of work, it can only be because entomology, like astrology, has ceased to have any physiological significance—a thing no entomologist will be willing to admit!

Mesilla, New Mexico, U.S.A. T. D. A. COCKERELL.

AN ARCHÆOLOGICAL SURVEY OF THE BRITISH ISLANDS.

THOSE who are interested in the preservation and examination of ancient monuments should read the plea for "An Archæological Survey of the United Kingdom," which formed the subject of Dr. David Murray's presidential address to the Archæological Society of Glasgow, and which is reprinted in a convenient form by James MacLehose and Sons, of Glasgow.

This is a succinct account of the existing laws relative to antiquities, and of the "rights" or otherwise of the public. "Government spends large sums of money every year upon the preservation and protection of our records, the reproduction of fading charters, &c., but it does not regard the monuments which illustrate or supplement these records. Archæologists have raised the veil that shrouds the first epochs of man's life upon the earth, and have given us a glimpse of prehistoric times, but Government does nothing to collect or preserve the material which is essential for such investigations. The editing and interpretation of our Runic monuments we owe to Prof. George Stephens, of Copenhagen. For a record of the Roman inscriptions in this country we have to look to Germany or to Canada. Inscriptions and sculptures are of the same character as written monuments, and it is surely just as important that these should be carefully collected and accurately transcribed and photographed as that we should have new editions of the Chronicles of the Picts and Scots, or of the Exchequer Rolls of Scotland.

"The quaternary period is common ground to the geologist and the archæologist, the physical characters are dealt with in the Geological Survey. But why should the systematic survey stop at this point, or be limited to the requirements of geological science? The monuments which are witnesses to man's presence, his life and labour, are surely as worthy to be collected and preserved as the fossil remains of extinct fauna and flora.

"The monuments of the past are not indeed wholly neglected by Government, for if an object be in itself artistic, in the opinion of the Science and Art Department, it has the sedulous care of that Department, and no money is grudged for its protection and reproduction. The Ardagh chalice, for instance, is of this description; but a Roman altar or a centurial stone, no matter how valuable it may be historically, is passed by. Can anything be more inconsistent? To limit ourselves to the artistic side of man's nature will give but a partial view. We wish to know his life as a whole, his surroundings, his pursuits, and manner of living—everything, in fact, that enables us to trace the growth and development of culture and civilisation. For this purpose the undesigned and unwritten records of the past must be systematically ascertained, protected, and preserved, and, if need be, copied or reproduced. To do this effectually Government assistance is essential as a first step. It is a work that has been too long neglected, and should be no longer delayed. Let us at once and for ever wipe away the reproach that England is the only country in Europe

that does nothing to register and protect her ancient monuments."

It may be urged that we have the Ancient Monuments Protection Act, which Sir John Lubbock, after great labour, succeeded in passing through Parliament. This Act is valuable so far as it goes, but only 69 monuments in the British Islands (29 in England, 21 in Scotland, and 19 in Ireland) were specified in the schedule. Under Section 10 of the Act of 1882, Her Majesty may, by Order in Council, make additions to the list of monuments protected by the Act. This power has, however, been taken advantage of only to a very limited extent. It has been exercised on six occasions between 1887 and 1892, and 31 monuments (7 in England, 17 in Scotland, and 7 in Ireland) have been brought under the Act. Dr. Murray definitely states that "the Government have, in fact, rendered the Act inoperative, as regards the future, by steadily declining to accept further monuments even when offered to them." Ireland has been more fortunate; there are thus between 170 and 180 monuments in Ireland under public protection, as against 38 in Scotland and 36 in England.

Dr. Murray is not alone in his desire to see all our archæological remains preserved and described; but he has stated the case with enthusiasm and full knowledge in this little brochure.

Specialisation in scientific studies is necessary, but there is a great danger of weakness through sub-division. For example, archæological remains are relegated to archæologists and antiquarians, who are tacitly held responsible for them. Why should not professed historians and all who desire to intelligently understand the culture history of their native land, as well as of mankind in general, feel that they too are responsible for the record and preservation of these historical data? Few branches of unapplied science are of more national importance, and it would be well if the wave of patriotism that is now astir could be partially diverted towards this truly patriotic object.

THE INTERNATIONAL PHOTOGRAPHIC CATALOGUE AND CHART.

IN the month of May last year the permanent Comité International, for the execution of the Photographic Chart of the heavens, met at Paris to discuss various questions which had been left undecided at previous Conferences, and to inquire into the state of progress of the work of the various observatories participating in this international scheme. At these meetings, in addition to the members of the Committee, several guests were invited to be present and take part in the discussions.

The report of the proceedings, which has just been published, commences with a brief reference to the work of each of the observatories that is partaking in this scheme, the President (the late M. Tisserand) stating that the undertaking, as a whole, was in a satisfactory state of advancement. The report then refers somewhat in detail to the numerous questions that had been prepared for discussion at these May Conferences, from which we make the following brief abstracts.

With regard to the catalogue, the first resolution adopted, as the result of a special Committee of inquiry, composed of MM. Donner, Dunér, Jacoby, Paul Henry and Scheiner, was that the probable error of the values of the rectilinear coordinates measured on the plates ought to be as small as possible, and that the measures should be made such that this error should not exceed $0''\cdot20$.

It was further resolved to publish, as soon as possible, the rectilinear coordinates of the stars photographed, and that this publication should also contain the data necessary for converting these results into equatorial coordinates. The Committee expressed the desire that a provisional catalogue of right ascensions and declinations might be published by those observatories whose resources were sufficiently large. Each observatory is allowed to choose the positions of those stars of reference in the catalogues which appear the most convenient to them. For the calculation of the constants of the *clichés*, a minimum, if possible, of ten stars of reference must be allowed, and the adopted positions of these stars should be published. It was decided to postpone to a later date the discussion relative to the question of using a uniform system of constants for all the observatories for the reduction of the stars to the epoch 1900. All agreed, however, that an identical form of publication for all the observatories should be adopted, that of the catalogue of the Paris Observatory serving as the type. Each observatory can determine the photographic magnitudes, either by means of measurement or by estimation. The only stipulation the Committee imposes is that the methods employed must be such that the magnitudes in different observatories can be reduced to a common system.

With reference to the so-called photographic chart, five resolutions were adopted, namely:—

(1) That each observatory will be provided with a scale (furnished by Captain Abney) of densities, which will be impressed on the plates simultaneously with the *réseau*, by which the sensibility of each plate for the luminous objects of different intensities will be controlled.

(2) For the construction of the chart, the second series of *clichés*—that is, those whose centres are of unequal declination—will be exposed three times for a period of thirty minutes each. The time of exposure may be diminished if a decided increase in the sensibility of the photographed plate be noticed.

(3) The Committee selects, as the best method of reproducing the chart, the photogravure on copper from the *clichés*, with three exposures on them, the original scale being doubled.

(4) Each observatory will make two contact glass positives of each negative, one of which will be preserved in the building at Breteuil, part of the Bureau International des Poids et Mesures.

The next meeting of the Committee will probably occur on the occasion of the Universal Exhibition, in the year 1900.

NOTES.

THE announcement of the resignation of M. J. de Morgan, Director General of the Administration of Antiquities of Egypt, recently made by a contemporary, will be received with regret by many. It will be remembered that the duties of this gentleman were two-fold; he was supposed to excavate sites which promised good antiquarian results throughout Upper and Lower Egypt, and also to direct and manage the Ghizeh Museum near Cairo. It is not clear whether M. de Morgan has resigned both duties, but a well-founded rumour asserts that he is going to leave Egypt and to excavate in Persia on behalf of the French Government, who are said to have obtained a concession to dig for antiquities throughout the country, and to have leave to carry away whatever they may find. Whether M. de Morgan has severed his connection with Egypt wholly or partially matters very little relatively, but his resignation brings to the front the important question of what is to be done in the future about the conservation of the monuments which remain *in situ*, and those which are preserved in the National Museum. No one can deny that M. de Morgan has worked well in Egypt, and although much fault has been found with his "Catalogue" by those who have carefully read the work, none can deny that his excavations have been both thorough and successful, and that he has

imparted new life to that branch of the Antiquity Department which is under his immediate control. Still, however, it is manifest that the Director cannot be both excavating and managing the Museum in Cairo at the same time, and that while the excavations have flourished the Museum has languished. All that could be done in the Museum by a subordinate official has been done by Brugsch Bey, whose archæological knowledge is first-rate; and what has been done is well done. But very much more needs doing, and when the new Museum is built, if it is to be a successful and useful institution, it must have an adequate staff, led by a permanent *resident* official, whose duty shall be to arrange, classify, label, and describe the various objects, and make them accessible to visitors under proper supervision. No Museum can flourish under the rule of a chief, who not only is non resident, but is for several months of the year away excavating sites which are remote from centres of postal and telegraphic communication. It is much to be hoped that the English authorities in Egypt will insist on the appointment of a director or keeper of the Museum, and of an official inspector and excavator; each official should have a "free hand" in his own department, and each should be answerable to some Minister of the Government only. The system hitherto followed has disheartened the staff, and has retarded the proper arrangement of the antiquities in the Ghizeh Museum.

Sir Archibald Geikie arrived in America a few days ago, intending to remain about one month, and to deliver the Williams course of lectures on geology at the Johns Hopkins University, Baltimore. A reception was given to him by the section of geology and mineralogy of the New York Academy of Sciences, and addresses were delivered by Prof. J. J. Stevenson, president of the Academy; Prof. Kemp, president of the section; by the secretary of the section, and by Mr. Heilprin, of Philadelphia. Sir Archibald Geikie responded, after which the members of the Academy and invited guests were presented to him individually.

A very important meeting of the Council of the American Association for the Advancement of Science was held at Washington a few days ago. Prof. Theodore Gill, vice-president of the section of zoology, succeeded to the office of president in succession to the late Prof. Cope, by virtue of his seniority, under the constitutional clause which devolves the duties of president upon the senior vice-president in such contingencies. As Prof. Cope had not prepared his annual address, Prof. Gill was requested by vote of the Council to deliver the presidential address in the form of an obituary of the late president, which he consented to do. Secretary Putnam read correspondence with Mr. Vernon Harcourt, conveying the invitation to all members of the American Association to attend the Toronto meeting on the same terms as to payment of dues as the members of the British Association; and to the officers of the Association to attend as honorary members. The Council authorised Secretary Putnam to return the thanks of the Association, and to invite foreign visitors to attend the meeting at Detroit, calling attention to the clause which admits them to honorary membership without payment of dues. It was also voted to invite such guests to register as honorary members of the several sections in which they are specially interested. Dr. L. O. Howard, of Washington, was nominated by the Council as vice-president for the section of zoology for the approaching meeting, in the place of the late Dr. G. Brown Goode. Secretary Putnam reported, as the result of a recent visit to Detroit, that the accommodations, both as to hotel headquarters and to place of meeting, were much superior to any before available. The new and spacious Hotel Cardillac will be the headquarters, and the immense new High School the place of all the meetings and gatherings. The school building has a hall capable of seating 2500 persons, and ample rooms for the sections.

The annual visitation of Greenwich Observatory will take place on Saturday, June 5.

Mr. J. Wolfe Barry, C.B., F.R.S., and the Council of the Institution of Civil Engineers, have sent out invitations for a conversazione to be held at the Institution on Tuesday, May 25.

It is stated in *Die Natur* that the valuable library of the late Prof. Du Bois Reymond has been purchased by the Prussian Government, and will be presented to the Berlin Physiological Society.

Dr. Kolle, of the Berlin Institute for Infectious Diseases, has (says the *British Medical Journal*) received a year's leave in order to proceed to Cape Colony, where he has been commissioned by the Cape Government to carry on the work of Prof. Koch. He will continue the investigation into rinderpest and leprosy, and organise stations for the study of those diseases.

We regret to see the announcements of the death of the following men of science:—Prof. Léon du Pasquier, of Neuchâtel, author of a number of papers on the glacial geology of northern Switzerland; Mr. Hugh Nevill, of the Ceylon Civil Service, known by his zoological observations and collections; Dr. Magitot, member of the Paris Academy of Medicine, and one of the founders of the Société d'anthropologie; Edmund Neminar, formerly professor of mineralogy and petrography at Innsbruck; Dr. L. Martin, professor of mathematics at Klausenberg.

The question whether the public has a right-of-way over the Giant's Causeway has just been decided in the negative by the Vice-Chancellor in the Dublin Courts. We have already noted that a syndicate had purchased the Causeway, and that their action in closing it against the public, who had had free access to it from time immemorial, caused great irritation. A Committee was formed to support the public rights, and some members of it asserted them by walking over the Causeway, with the result that an injunction was asked for to restrain further trespass. A right-of-way was pleaded; but the Vice-Chancellor held that as the Causeway did not lead to any public place, this plea could not be upheld. It is stated that an appeal will be lodged against this judgment.

At the sixty-fifth annual meeting of the British Medical Association, to be held at Montreal from August 31 to September 3, inclusive, an address in Medicine will be given by Prof. W. Osler, an address in Surgery by Mr. W. M. Banks, and an address in Public Medicine by Dr. Herman M. Biggs. The president-elect is Dr. T. G. Roddick, professor of surgery in the Gill University, Montreal, and the sections, with their presidents, are as follows:—Medicine, Dr. Stephen Mackenzie. Surgery, Mr. Christopher Heath. Public Medicine, Dr. E. P. LaChapelle. Obstetrics and Gynæcology, Dr. W. J. Sinclair. Pharmacology and Therapeutics, Dr. D. J. Leech. Pathology and Bacteriology, Mr. Watson Cheyne, F.R.S. Psychology, Dr. R. M. Bucke. Ophthalmology, Mr. Edward Nettleship. Laryngology and Otology, Dr. Greville Macdonald. Anatomy and Physiology, Dr. Augustus D. Waller, F.R.S. Dermatology, Mr. Malcolm Morris.

It has been arranged shortly to hold a Conference of the members of the Institution of Civil Engineers in London, under conditions which, it is hoped, may be convenient to many who are precluded from attending the weekly meetings during the Session, and may prove serviceable to all by the discussion of a wider range of subjects than can be dealt with on ordinary

occasions. It is intended that the business of the Conference should differ from the ordinary proceedings of the Institution, in that papers descriptive of works executed should give place to brief statements concerning important debatable matters in engineering science and practice, introduced with a view to elicit discussion on the questions raised. This Conference is fixed for May 25, 26 and 27, the morning of each day (from 10.30 to 1.30) being devoted to the consideration of the above statements, and arrangements being made for inspections of engineering works in the afternoon. The work of the Conference will be carried out under the direction of the Council, with the assistance of seven sectional committees, consisting of members of the Institution, representative of various localities in the United Kingdom, and identified with the several branches of engineering. The sections and their chairmen are :—Railways: Sir Benjamin Baker, K.C.M.G. Harbours, Docks, and Canals: Mr. Harrison Hayter. Machinery and Transmission of Power: Sir Frederick Bramwell, Bart. Mining and Metallurgy: Mr. T. Forster Brown. Shipbuilding: Sir William H. White, K.C.B. Waterworks, Sewerage, and Gasworks: Mr. Mansergh; Applications of Electricity, Mr. Preece, C.B.

ENGLISH weather is as fruitful a subject for composition as it is a theme for conversation. Like many other people, Mr. C. A. Whitmore, M.P., is a devoted student of our meteorology, so that what he writes about it in the May number of the *National Review* is worth reading. Weather fallacies have been exposed times without number, but they are so deeply rooted in the minds of the unscientific that it may be doubted whether they will ever be completely eradicated. Mr. Whitmore throws doubt upon the popular impression that the changes of the moon synchronise with marked changes of weather. The few facts he states as to weather and lunar phases since the beginning of last summer, ought to convince people that their faith in the influence of the moon is misplaced. Another very common idea is that a heavy dew at night presages a fine day on the morrow; whereas it only indicates that the sky is clear and conditions are favourable for the deposition of dew. At certain times of the year a heavy dew is a sign of unstable rather than of stable weather. A luxuriant crop of berries in the autumn is said to forebode a severe winter; but the people who believe this, forget, or do not know, that the berries tell of conditions which have passed rather than of those to come. The temperature, sunshine, rainfall, abundance of insects, and other past causes which affect the birth and growth of plants, decide whether the berries shall be few or many, and not the future conditions. It is a beautiful sentiment to think that many berries are provided to furnish food for birds in a hard winter; but, unfortunately, nature does not furnish facts to support it. Having disposed of these and several more items of weather-lore, Mr. Whitmore supplies meteorologists with a few weather signs gained by his own observation and experience.

THE International Aeronautical Committee of Paris and Strassburg have proposed Thursday, May 13, at 3.30 a.m. local time, for the third international balloon ascents. This early hour of sending up unmanned balloons is proposed in order to study the true temperature of the air during the first part of the ascent; while the influence of solar radiation will be from the records obtained during the second part of the time. The results of the experiments of November 14 and February 18, showed that the thermometers were not sufficiently protected in the horizontal part of the trajectory, in which the ventilation is least active; hence it has been deemed necessary to make an important part of the ascent while the radiation of the sun is too weak to have any serious influence upon the thermometric results.

JAPAN is usually regarded as the country of earthquakes; but, if we take area into account, it would seem that shocks are still more numerous in Greece and the adjoining islands. Under the able superintendence of Dr. S. A. Papavasiliou, a geodynamic section of the Observatory of Athens was founded in 1893, and, since the summer of 1895, the seismic organisation of the country has been actively at work. About a year ago, the publication of monthly bulletins was commenced with the number for January 1896, and the number for last December has been issued recently. The notices are nearly always very brief, and it is sometimes uncertain whether they refer to different shocks, or to observations of the same shock at different places. Making allowance for these cases, it would appear that the total number of earthquakes felt in the kingdom during 1896 was 529, or very nearly $1\frac{1}{2}$ a day. Of this number, no fewer than 306 were recorded in the island of Zante alone.

THE property acquired by gases, after being traversed by electric sparks, of cooling heated bodies as if the gases had become better conductors of heat, forms the subject of a short note by Prof. E. Villari (*Rendiconti della R. Accademia di Napoli*). The phenomenon was observed by studying the action of different gases on a platinum spiral heated to redness by the electric current, the sparks being produced by a powerful coil reinforced by large Leyden jars. In some cases, the apparent cooling produced a fall of resistance of 10 per cent. Under similar conditions, the effect was nearly the same for oxygen, nitrogen, and air, but was much less marked in the case of hydrogen. It increases with the energy of the sparks, and also, at first, with the temperature of the spiral; but after this exceeds a certain limit, the refrigerating power decreases. Experiments made with a similar apparatus, with a view of testing whether Röntgen rays modify the thermal conductivity of the gases they traverse, have as yet given negative results.

UNDER the title of "Versuche über Hyperphosphorescenz," Profs. Elster and Geitel publish an interesting note on the invisible radiations from salts of uranium, discovered by Becquerel. The authors confirm Becquerel's statements as to the physical properties of these rays, and the fact, already noted in these columns (vol. xxxv. p. 119), that the salts may be kept in the dark for months without the radiation ceasing, so that the source of radiant energy is at present unknown. Uranium sulphate and sulphate of uranium and potassium are photo-electrically inactive, and the radiation is not materially promoted by sunlight. On the other hand, aluminium, zinc, luminous paint, and fluor spar, when light falls on them, do not, like these salts, emit dark radiations of sufficient intensity to impart electrical conductivity to the surrounding air. The conclusion is, that the present phenomena cannot be attributed to hyperphosphorescence. Profs. Elster and Geitel's paper is published in the *Jahresbericht des Vereins für Naturwissenschaft zu Braunschweig*, No. 10 (Brunswick, 1897).

IN a note in NATURE (December 31, 1896, p. 206) attention was drawn to an essay, by Prof. E. S. Morse, on problematical bronze or iron objects found in Greek, Roman and Etruscan tombs. Prof. D. G. Brinton (*Science*, 1897, p. 614) identifies the so-called "bow-puller" with the Greek myrmex (μύρμηξ) which, in pugilistic encounters, was strapped or chained on the hand over the leathern cestus.

THE large number of interesting Romano-British objects found in Thirst House Cave in Derbyshire, prove that this cave must have been occupied for a long period. It is unfortunate that, as in so many other instances, this important cave should not have been scientifically excavated. Casual cave-digging cannot be too strongly deprecated, as caves afford most valuable data for relative chronology, and it is a pity to have such

important opportunities sometimes wasted by curiosity-hunters. Thirst House is probably derived from "The Hurst House," or the house in the wood. An interesting and illustrated account of the find is given, by J. Ward, in *The Reliquary and Illustrated Archæologist* (1897, p. 87).

F. H. CUSHING, in the *American Anthropologist* (vol. x. p. 17), suggests that the artificial deformation of the skull, like other mutilations of the person, were designed to liken a man either to his totem or to the animal whose distinguishing traits were essential to the office held by the man, and thus to confer through actual physical resemblance ideally conceived animal powers. The evidence Mr. Cushing adduces from America lends some support to this view, which may be an explanation of some, if not of all, the mutilations that have occurred in America. This theory is worth bearing in mind when considering analogous facts in other parts of the world.

THE question of suppressing the rabbit pest in Australia by employing the microbes of chicken cholera for their destruction, has been recently again brought prominently forward by the publication of an able report by the Government bacteriologist, Mr. C. J. Pound. This idea owes its origin, in the first instance, to Pasteur; but one of the principal objections raised at the time to its adoption in New South Wales was the reluctance felt to introduce a new disease, and one hitherto unknown in the Colony. Mr. Pound, however, commences his official document by the announcement that he has discovered the existence of chicken cholera in Queensland and New South Wales; and he describes in detail the various scientific investigations which he has made, placing its identification beyond all question. Experiments on a large scale were carried out last year to test the efficacy of this method of destroying rabbits; and the results were so encouraging, that the Government has been recommended to grant permission to farmers and others, who suffer from the depredations of these animals, to utilise this means of suppressing them. It has been calculated that two gallons of broth infected with chicken-cholera microbes added to pollard, is sufficient to destroy at least 20,000 rabbits, irrespective of infection induced by contagion. As, however, pellets of pollard infected with these microbes are rendered completely innocuous after three hours' exposure to the direct rays of the sun, the distribution of the morbific material over the fields is recommended to take place either just before or after sun-down.

THE Vermont Botanical Club, organised two years ago, now numbers sixty active members. It is vigorously prosecuting a botanical survey of the State.

WE have received the eighth part of vol. i. of the "Records of the Botanical Survey of India," consisting of a note on the botany of the Baluch-Afghan Boundary Commission of 1896, by Mr. F. P. Maynard and Mr. D. Prain.

A SECOND Appendix for 1897 of the *Kew Bulletin of Miscellaneous Information* is devoted to a list of plants brought into cultivation for the first time during the year 1896, or re-introduced after having been lost from cultivation. The list includes over 300 species.

THE recently established New York Botanical Garden is on a very large scale. The buildings, with decorative approaches and surroundings, will cover 25 acres; pines and other coniferous trees, 30 acres; deciduous trees, 70 acres; natural forest, mostly undisturbed, 25 acres; shrubs and small trees, 15 acres; herbaceous ground for scientific arrangement, 8 acres; bog garden, 5 acres; lakes and ponds, 6 acres; meadows, 10 acres. The museum building will have a frontage of 304 feet, with two wings each 200 feet in length.

THERE are several ways of cultivating interest in science, and not the least serviceable of them are works of fiction into which scientific facts and problems are woven. Mr. H. G. Wells commences a new story in the April number of *Pearson's Magazine*, entitled "The War of the Worlds," and its chief idea is an attack which inhabitants of Mars are supposed to make upon the earth. It is evident from many paragraphs that Mr. Wells reads his NATURE, and closely follows the planetary observations described in our astronomical column from time to time.

A NUMBER of our readers will be glad to have their attention called to the advertisement, appearing in another column, of a cruise to the capitals of the Baltic, visiting Christiania, Copenhagen, Stockholm (for the exhibition), and on to St. Petersburg for a seven days' sojourn in Moscow, returning by the Baltic Canal. The cruise is by the Albion Steamship Company's steam yacht *Norse King*, and starts from Newcastle-on-Tyne on May 22, returning on June 19.

THE extensive use of induction coils in surgical and physiological work with Röntgen rays, has created a demand for a practical book which shall show medical men, and others who have entered the new field of experiment, how to make the best use of their instruments. Mr. Lewis Wright, the author of well-known books on experimental optics and optical projection, has prepared a work of this kind, and it will be published in a few days by Messrs. Macmillan and Co. under the title, "The Induction Coil in Practical Work, including Röntgen X-Rays."

AMONG the noteworthy papers and other publications which have come under our notice within the past few days are the following:—The *Comptes rendus* of the works presented at the meetings of the Société Helvétique des Sciences Naturelles, held at Zermatt in 1895, and at Zürich in 1896; also the *Actes* (*Verhandlungen*) of the same meetings. The London agents of these publications are Messrs. Williams and Norgate.—"Le Climat de la Belgique en 1896" (pp. 190), by A. Lancaster. This essay is an excerpt from the *Annuaire* of the Royal Observatory at Brussels for 1897.—The third part of the Report of the International Meteorological Congress held at Chicago in August 1893 (pp. 585-772), edited by Oliver L. Fassig (*Bulletin* No. 11, U.S. Department of Agriculture, Weather Bureau). The report contains twelve papers on climatology, and ten on instruments and methods of investigation. All the papers are in English, and together they make a collection which British meteorologists will highly value.—*Proceedings* of the American Association for the Advancement of Science, for the meeting held at Buffalo in August 1896 (pp. 269). The addresses of the retiring President, Prof. E. W. Morley, and of the Presidents of the different Sections are printed in full, but only the titles of the papers read are given.—*Proceedings and Transactions* of the Nova Scotian Institute of Science, 1895-96. Among the subjects of the papers are the calculation of the conductivity of mixtures of electrolytes, and Nova Scotian undeveloped coal-fields, geology, and Orthoptera.—*Bulletin* of the American Museum of Natural History, vol. viii., 1896 (pp. 327). Several of the articles in this publication have already been noticed in NATURE, from authors' separate papers. Attention may, however, usefully be called to papers on alleged changes of colour in the feathers of birds without moulting, catalogue of meteorites in the American Museum of Natural History, the temple of Tepoztlan, Mexico (illustrated by five plates), descriptions of new North American mammals, notes on birds observed in Yucatan, and transformations of some North American Hawk-Moths.—*Atti della reale Accademia delle scienze fisiche e matematiche di Napoli*, second series, vol. viii., 1897. Eleven memoirs are included in this volume, and among the subjects dealt with are: a class of equations with derived partials, microscopic changes in nerve cells due to functional activity, and under the action of

stimulating and destructive agents; earth currents recorded at the Vesuvius Observatory in 1895, and the history of Vesuvius from 1875 to 1895; a mathematical investigation of the lines of nodes of vibrating membranes; the geology of the Southern Appennines (this elaborate paper occupies 128 pages); the alternate current transformer with a condenser in the secondary circuit; the physical constitution of the atmosphere, from the results of observations made during eight balloon ascents by James Glaisher, also a new formula for the calculation of altitude from barometric observations.—In the *Rendiconti del Reale Istituto Lombardo*, Prof. Luigi de Marchi gives a mathematical investigation of the effect of viscosity on the movements of glaciers.

NOW that acetylene can be readily prepared in the laboratory, many new uses will no doubt be found for it. The most recent proposal in this connection is that made by H. G. Söderbaum, in the current number of the *Berichte*. It appears that the gas can be employed for the quantitative precipitation of copper in ammoniacal solution, and for its separation from metals like zinc, which are not precipitated by ammonia. Acetylene possesses the great advantage over sulphuretted hydrogen, which is usually employed for this purpose, that it yields a precipitate which can be filtered and washed very rapidly, and which does not easily become oxidised and pass into solution. The washed precipitate is finally decomposed by dilute nitric acid, the solution filtered and evaporated to dryness, and the residue ignited and weighed as oxide.

THE additions to the Zoological Society's Gardens during the past week include an Orang-outang (*Simia satyrus*, ♂) from Borneo, presented by Captain Francis R. Pelly, R.N., H.M.S. *Porpoise*; a Bonnet Monkey (*Macacus sinicus*, ♂) from India, presented by Mrs. Douglas; a Rhesus Monkey (*Macacus rhesus*, ♂) from India, presented by Mr. P. A. Ledger; a Mongoose Lemur (*Lemur mongoz*) from Madagascar, presented by Mr. P. Baxter; a Grey Ichneumon (*Herpestes griseus*) from Ceylon, presented by Surgeon-Major C. Seymour; a Chimpanzee (*Anthropopithecus troglodytes*, ♀), a Black Gallinule (*Limnocorax niger*) from West Africa, presented by H.E. Colonel F. Cardew, C.M.G.; two Himalaya Goldfinches (*Carduelis caniceps*, ♂ ♀) from India, presented by Mr. Frank Finn; two Egyptian Geese (*Chenalopex ægyptiacus*, ♂ ♀) from Africa, presented by Mr. A. E. Speer; a Mauge's Dasyure (*Dasyurus viverrinus*) from Australia, presented by Mr. J. C. Chipper; a Peacock Pheasant (*Polyplectron chinquis*, ♂) from British Burmah, presented by Mr. Charlton Parr; a Burrhel Wild Sheep (*Ovis burrhel*, ♀) from the Himalayas, a Reed Buck (*Cervicapra arundinum*, ♂) from the Limpopo River, South-east Africa, a Sing-Sing Water Buck (*Cobus unctuosus*, ♂) from West Africa, a Somali Wild Ass (*Equus somilicus*, ♂), a Somali Ostrich (*Struthio molybdophanes*, ♂) from Somaliland, six Pintails (*Dafila acuta*, 3♂, 3♀), European; two Smith's Partridge Bronze-winged Pigeons (*Geophaps smithi*, ♂ ♀) from Australia, two White-headed Woodpeckers (*Leuconerpes candidus*) from Brazil, two Wreathed Hornbills (*Rhytidoceros undulatus*) from Borneo, a Silky Cow Bird (*Molothrus bonariensis*) from South America, purchased.

OUR ASTRONOMICAL COLUMN.

A REMARKABLE RELATION BETWEEN THE DISTANCES, MASSES, AND SURFACE GRAVITIES OF THE PLANETS.—In the *Bulletin Astronomique* for April, M. P. Berthot describes an ingenious empirical law which approximately connects the mean radii (R) of the orbits, the masses (m), and the values of g at the equators of the different planets. By employing a graphical method in which the abscissæ represent the values of gravity (p), and the ordinates those of $\frac{R}{m}$, all the planets, with the exception of Mercury, fall very approximately on an ellipse, $\frac{R}{m}$ being considered negative for all values of p greater or equal to 1, and the unit value of p being that at the surface of the earth.

If $\frac{1}{p}$, instead of p, be used as the abscissæ, the ellipse becomes then an equilateral hyperbola, and if the logarithm of $\frac{1}{p}$ be substituted, the same becomes a parabola. The following table gives the true and calculated values of p for one of the three curves, namely, the ellipse, computed by M. Berthot, those for the hyperbola and parabola showing somewhat greater errors per cent. in the case of Mercury. These latter are not referred to below.

	$\frac{R}{m}$	p (true).	p (calc.) ellipse.	Error for 100.
Mercury ...	6·350	0·439	0·502	14·3
Venus	0·919	0·802	0·803	0·1
Earth	1·000	1·000	1·000	0·0
Mars	14·510	0·376	0·375	0·3
Jupiter ...	0·017	2·261	2·284	1·0
Saturn	0·103	0·892	0·877	1·7
Uranus ...	1·414	0·754	0·764	1·3
Neptune ...	1·824	1·142	1·120	2·0

To make Mercury conform with the values calculated by the above-mentioned formulæ, it is suggested that either the old value of the mass determined by Le Verrier (0·0715) must be adhered to (contrary to more recent investigations), or, if the mass $\frac{1}{9,700,000}$ be retained, the diameter of the planet must be assumed to be one-quarter too large by the phenomenon of irradiation.

THE DOUBLE STAR 44 BOÖTIS.—This star, which was discovered on August 17, 1781, by Herschel, has recently (*Monthly Notices*, vol. lvii. No. 5) been pointed out by Mr. Burnham in consequence of the singular and remarkable arrest of the relative motion of the two stars. For a period of thirty years these stars gradually increased their distance from one another at a nearly uniform rate, the position angle at the same time slowly advancing. After this, for a period of equal length, the motion had apparently been arrested, and "down to the present time, they have remained absolutely at rest, so far as one can tell from full and careful sets of measures by the best double-star observers." This is a remarkable system, which evidently is unique among the known binaries, and, as Mr. Burnham points out, it is not easy to account for such a state of affairs. He remarks, however, that the usual dark-body hypothesis will readily suggest itself; and it is easy to imagine one of these stars with an invisible companion, both moving in a very eccentric orbit in a plane parallel to the line of sight, and to select a period and direction of motion that will not only explain the motion, but the absence of motion shown by the observations of the visible components, and "when this is presented with the usual refinements of computation, doubtless for the time being a plausible case could be made out." It will be interesting to watch this binary, and see, when the relative motion has been resumed and a decided change of position has taken place, whether an accurate, or even approximate, orbit can be obtained. The case is decidedly a unique one for double-star observers; and as there seems to be no question about the observations themselves, the steady change of position and subsequent arrest being based on "unimpeachable observations by the best observers," special interest will be attached to future measurements.

REPORT OF MR. TEBBUTT'S OBSERVATORY.—The energetic proprietor of this observatory presents a most satisfactory report for the year 1896, the amount of work accomplished being unusually large, owing to the very great number of clear nights experienced. The meridian work consisted chiefly in observing stars with the 3-inch transit instrument for checking the sidereal chronometer, which was used as timekeeper throughout the year. The observations of occultations of stars by the moon, made with the 8-inch equatorial, are stated to be the richest obtained in any one year since the foundation of the observatory. Other observations included 810 comparisons of minor planets with the filar micrometer, the phenomena of Jupiter's satellites, double and variable stars, and the regular meteorological work. The report states that all the astronomical and nearly all the meteorological observations were made by Mr. Tebbutt himself,

but during a day's absence from home, about once in three weeks, the meteorological observations were made by his son. In some of the reductions the services of Mr. R. B. Walker were engaged. Quite recently a discussion of the early series of occultation observations made in the years 1864 to 1870 at this observatory, has been concluded by Dr. Hugo Clemens, of Göttingen, in his inaugural dissertation, with a most satisfactory result, which speaks well for the observations employed.

THE TWELFTH GERMAN GEOGRAPHICAL CONGRESS.

THE German "Geographentag," which takes place every second year, was held from April 21 to 23, in Jena. The meeting was attended by over five hundred persons from all parts of Germany, including Prof. Brackebusch, Colonel Frobenius, Prof. Karl Futterer of Karlsruhe, Prof. Gerland of Strassburg, Prof. Hahn of Königsberg, Dr. Hassenstein, Dr. K. Hassert, Herr von Hesse Wartegg, Prof. Kirchhoff of Halle, Captain Kollm (Secretary of the Berlin Geographical Society), Dr. Kretschmer, Count von Linden, Dr. Lindeman, Dr. Hans Mayer, Prof. Neumann of Freiburg, Prof. Neumayer of Hamburg, Dr. Schenck, Prof. Supan of Gotha, Prof. Sievers of Giessen, Prof. Wagner of Göttingen, Prof. Walther of Jena, Prof. Wahnschaffe of Berlin, and Count von Zeppelin. Twelve German Geographical Societies were officially represented, and two foreign Societies—the Royal Geographical Society and the Hungarian Geographical Society—sent delegates.

The town of Jena was decorated for the occasion, and the geographers were warmly received and handsomely entertained. Five meetings were held for the reading and discussion of papers, and each evening there was a social gathering, usually of an informal and genial character.

At the first meeting, after addresses of welcome had been given on behalf of the Grand Duke of Saxe-Weimar, the Municipality of Jena, and the University, the President, Prof. Neumayer, of the German Naval Observatory at Hamburg, delivered a short opening address, and then proceeded to present the Report of the German Committee on South Polar Exploration. He referred in the most generous manner to the approaching Belgian expedition, and to the projected British expedition, under the auspices of the Royal Geographical Society, but urged the importance of a national German undertaking, pointing out that there was scope for many expeditions, simultaneous or consecutive, in the vast unknown areas of the far south. The Committee appointed at the "Geographentag" at Bremen, in 1895, to arrange for a German Antarctic Expedition, had drawn up a comprehensive scheme, but the means with which to carry it out were still wanting. The aims of the expedition were defined as the study of meteorological conditions, terrestrial magnetism, geodesy, zoology, botany, geology, and ice-conditions, as well as geographical exploration. The expedition must, as an essential condition, winter for two years within the Antarctic Circle, while a second vessel carries on hydrographic work on the edge of the ice. The Committee had selected the longitude of Kerguelen Island as the most suitable point for attempting to force a way southward. The co-operation of the observatories in Cape Town, Melbourne, and in Mauritius would give special value to the meteorological and magnetic observations made in the selected part of the Antarctic area. Two vessels of about 400 tons would carry each four officers, four of a scientific staff, and a crew of twenty-two. The whole cost is estimated at under 50,000*l.*, and a strenuous appeal will be made to the German people to subscribe this sum, as soon as the important step of selecting a leader for the expedition has been taken.

The remainder of the first sitting was occupied by papers descriptive of explorations in Brazil by Dr. Hermann Mayer, and in Asia Minor by Dr. Zimmerer and Herr Roman Oberhummer.

The second sitting was devoted, as required by the rules of the Congress, to educational subjects, the most important paper being by Prof. Fischer, on the importance of geographical tours of considerable extent under the guidance of geographical instructors.

The third sitting was devoted to geo-physical questions. Papers on seismic observations were read by Prof. Gerland of Strassburg, and Prof. Supan of Gotha, both of whom dwelt on the urgent importance of establishing systematic seismological observations in all parts of the world. A lively discussion ensued, and Prof. Supan formulated a resolution, which was subsequently adopted, to the effect that the establishment of seismic observations in all countries should no longer be postponed, and that the "Geographentag" hoped that the German Government would take the necessary steps without delay to establish a system of observations in Germany similar to that which had been established and carried out with valuable results in Japan. Dr. Schmidt, of Gotha, read a paper on the geographical problems connected with the study of terrestrial magnetism, and Dr. Naumann, of Munich, spoke of the relation between the magnetic conditions and the geological and geo-tectonic character of a region, illustrating his remarks by reference to his own studies when engaged on the geological survey of Japan.

The fourth sitting was devoted to zoogeography, Dr. Semon, of Jena, discussing the fauna of Australia in the light of his recent researches. Prof. Hahn, of Königsberg, spoke of the distribution of transport animals, and the influence exerted by geographical conditions on the method of transporting goods on land. Dr. Schneider, of Dresden, read a paper on the fauna of the island of Borkum, to which he has devoted ten years of study, and has distinguished an immense number of species and varieties which had not previously been recognised.

At the fifth and concluding sitting, various resolutions arising out of the papers were proposed and voted upon. Breslau was selected as the place of meeting for the thirteenth "Geographentag" in 1899; and Prof. Walther, of Jena, read an important paper on the interpretation of Thuringian scenery by means of the geological structure of the district. He had previously, in the Geological Museum, demonstrated the geology of Thuringia by means of an ingeniously constructed model, which showed the somewhat complicated geological history of the neighbourhood in a strikingly graphic and simple manner.

By special invitation the geographers were shown over the great optical works of Messrs. Zeiss, and had an opportunity of seeing the whole process of the working of lenses and prisms, and the construction of the numerous forms of scientific instruments which are produced in the establishment. Excursions were also made to various places of interest in the neighbourhood, the geology and archæology of which were explained by competent guides.

A word must be said as to the social arrangements, which were of the happiest kind. At the dinner and "Festcommers," given by the town, a number of original geographical songs, composed by Prof. Leo Sachse, were sung, the allusions exciting much amusement amongst the visitors. After the dinner, Usambara coffee and Cameroons cigars were served, as an example of the increasing importance of the German colonies. Altogether the meeting presented an impressive picture of the solid work in scientific geography being carried on in Germany, and of the enthusiasm which professors and students alike bring to bear on the problems they attack.

THE INSTITUTION OF MECHANICAL ENGINEERS.

AN ordinary general meeting of the Institution of Mechanical Engineers was held on Wednesday and Friday evenings, April 28 and 30, the President (Mr. E Windsor Richards) occupying the chair. Two papers were read—the first, on "Mechanical Propulsion on Canals," by Mr. L. S. Robinson; and the second, on "Experiments on Propeller Ventilating Fans and on the Electric Motor Driving them," by Mr. W. G. Walker.

Mr. Robinson's paper was of practical rather than of scientific interest. The most striking point brought out by the author was that it requires no more power to tow a long barge than a short one on a canal, an "enigma," to use an expression Mr. Henry Davy applied during the discussion, which neither the author nor the speakers at the meeting were able to explain. Mr. Robinson was of opinion that the chief point to be observed in canal navigation is the cross section of the canal. Shallow water is fatal to efficiency. This was borne out generally by the speakers during the discussion, Sir Leader Williams stating that it was useless to attempt improvements in mechanical details of tugs, &c., until the waterways were of a design that enable these improvements to be applied with advantage. A description was given of certain experiments made on a hydraulically propelled boat, fitted with a discharge orifice that passed through the stern-post of the vessel, and had a constricted passage, something of the nature of a *vena con-*

tractor, although differing from the latter form to a certain extent. With the discharge orifice of this form a fair speed was obtained, whereas with ordinary discharges the boat could hardly be moved along.

The Rev. Mr. Capell, the originator of this discharge nozzle, gave particulars of the experiment made with the vessel, and concluded that the success of jet propulsion depended on the form of the discharge nozzle. The particulars given were not sufficiently detailed to enable the problem to be adequately discussed, and it would be requisite to know, before arriving at any conclusion, whether the observations taken were properly verified, and the recording instruments were sufficiently trustworthy for implicit reliance to be placed upon them.

Mr. Walker's paper was on an interesting subject, and some of the experiments which he showed were of a practical nature. They will be doubtless useful to those not acquainted with the details of this field of research. The question of relation of speed, power absorbed, and air discharged with propeller ventilating fans was discussed. Seventeen three-bladed fans were tried, being driven by a continuous-current series-wound electrical motor of about one-third electrical horse-power. The current was taken off the mains of the Westminster Electric Supply Corporation. The fans were run at a speed up to six hundred revolutions a minute; the velocity of the air was measured by an anemometer. The results, which are too voluminous to quote in full, were contained in tables attached to the paper. The effect of cross section of fan-blades was discussed in the paper. The blades were of sheet-iron; all, excepting one, of 1/16 inch thick. Their cross sectional lines were all composed of straight lines or arcs of circles. The fans in each group differed from one another only in the cross section of their blades, which were flat, plano-convex, or concavo-convex of different degrees of curvature. A notable feature of the experiments made by the author was that the effect of putting a curved surface upon the back of a flat-bladed fan, thus giving a plano-convex section, was to increase the mechanical efficiency 28 per cent., the volumetric efficiency 54 per cent., and the pressure efficiency 1·4 per cent. The angle of the blades was 17°. The most efficient fan of the group was one having a blade concavo-convex in section with a hollow space between the faces, when the mechanical, volumetric, and pressure efficiencies were respectively 28, 65, and 2·1 per cent. The efficiencies were thus increased by making the blades thicker in the middle of their breadth. To test the effect of feeding the fans from the tips of the blades the delivery tube through which the air was passed was moved forward, the fan thus being outside the tube. This increased the mechanical, volumetric and pressure efficiencies from 16·9, 62·0, and 2·0 to 29·4, 78·0, and 3·1 per cent. respectively. The velocity of air on entering and leaving the fans was measured by the anemometer. Experiments were made to test the effect of a contracted outlet and inlet. The fan worked partly in a delivery tube, the outer end of which was partially closed by plates with holes of varying sizes. The efficiency was naturally much reduced. It was anticipated that the slow speed of the blades near the centre partly accounted for this, and a circular disc was therefore fixed in front of the fan on the delivery side. This prevented the air passing back again through the centre of the fan, which it might do owing to the slow speed, and the efficiency was raised. The more the delivery orifice was closed, the larger had to be the disc.

Without entering into theoretical views as to the action of the blades, the author stated that, having regard to the stream-line principle, the section of the blades should be as ship-shape as possible. The two losses in an air-propeller are rotary motion imparted to the air, and skin friction of the blades. The loss from the latter cause was found to be comparatively small by means of experimenting with flat thin blades set at a plane coinciding with the plane of rotation.

The summer meeting of this Institution will be held this year in Birmingham, during the last week in July.

ANNUAL MEETING OF THE U.S. NATIONAL ACADEMY OF SCIENCES.

THE National Academy of Sciences held its annual meeting at Washington, April 20-22, with about the usual attendance of members, but a marked paucity of papers, only fourteen having been read, of which number five were biographies. These were of Dr. G. Brown Goode, by Prof. S. P. Langley; of Prof. Thomas L. Casey, by Prof. H. L. Abbot: of Prof. Charles E. Brown-Séquard, by Prof. H. P. Bowditch (by title); of Prof. Hubert A. Newton, by Prof. J. W. Gibbs; and of Mr. George H. Cook, by Prof. G. K. Gilbert.

An experimental study on the influence of environment upon the biological processes of the various members of the colon-group of bacilli, by Dr. Adelaide Ward Peckham, was presented by Prof. J. S. Billings.

Prof. T. C. Mendenhall read a paper on the energy involved in recent earthquakes. He also read a paper on a ring pendulum for absolute determinations of gravity, giving results of a suggestion of Mr. A. S. Kimball that a disc of metal vibrating in its own plane would constitute an improved apparatus for such determinations. This gives the equivalent of a pendulum of any length from infinity to that of the diameter of the outer circumference of the ring. The ring is suspended from its inner circumference; and the length of the equivalent pendulum is computed by the following formula, in which l is the length required, R is radius of the outer, and R_2 is that of the inner circle:—

$$l = \frac{R^3 + 3R^2}{R_2}$$

With a crudely prepared disc of this description, results were obtained correct to one part in 10,000.

Prof. S. C. Chandler read a paper on variation of latitude, a full abstract of which will appear in NATURE. He also presented another paper on variation of latitude and constant of aberration from observations at Columbia University, by Messrs. J. K. Rees, H. Jacoby, and H. S. Davis. These observers report a series of observations extending from May 9, 1893, till June 14, 1894, divided into groups of from 30 to 100. They confirm Chandler's period of about 427 days. They also fix accurately the latitude of the observatory of Columbia University, which is 40° 48′ 27″·195.

Prof. A. A. Michelson gave a description of a new harmonic analyser, an apparatus devised by him, which enables him to integrate in a few minutes long and difficult problems such as would require weeks for mathematical solution.

In his paper on the position of the Tarsiids and relationship to the phylogeny of man, Prof. Theodore Gill maintained that man is more nearly allied to the chimpanzee and the gorilla than to the orang-outang; the abbreviation of arms and loss of cranial ridges having been caused by disuse of arms for tree climbing, and of teeth for crushing branches, &c., so that powerful facial muscles were no longer required, nor the ridges to which they were attached. The teeth also approached more closely together, filling up the gaps in jaw of apes. Children still show ancestral type in disproportionate length of arm.

Prof. A. Agassiz read a paper on some recent borings in coral reefs, in which he maintains that the old Darwinian theory of subsidence is no longer tenable, as that would require a thickness of 2000 feet in such reefs, but in most cases examined the thickness was within 130 feet. Observations include the Yucatan atoll, about 30 fathoms; Solomon Islands, 125 to 130 feet; Florida elevated reef, 60 feet, but this has been denuded and may have been originally of twice this thickness; along the coast of Cuba, 145 feet. Prof. Agassiz attempted to measure the thickness of the great coral reef near Australia, which is 1500 miles long, and 50 to 75 miles wide; but could not yet obtain accurate results. He is confident, however, that the thickness of it is only 25 to 30 fathoms. Prof. Agassiz concludes, however, that barrier, fringing and atoll reefs are none of them thick.

Prof. A. W. Wright read a paper on some recent experiments in Röntgen rays. By using plane glass he obviates the misleading action of a prism in which the thick part absorbs rays, and indicates an apparent negative index of refraction. No indication of refraction was found, however, in using plane glass arranged at an angle so that it would refract rays of light. A thin beam of X-rays was also passed between the poles of a powerful magnet. The poles were then reversed, but no change in the direction of the rays could be detected. Some very recent experiments, however, which he has not yet fully verified, seem to show that perhaps these rays may be diffracted, even if not capable of being refracted. The conjecture is due to the fact that, on passing the beam through a platinum net-work in the manner described, faint interference lines seemed to be produced.

Prof. Asaph Hall was elected vice-president; Prof. Ira Remsen, home secretary; and Prof. A. Graham Bell, treasurer. New members elected were Messrs. Wm. H. Dall (of Washington); Frank A. Gooch (of Yale); Chas. S. Minot (of Boston); and E. W. Morley (of Cleveland).

The autumn meeting of the Academy will be held at Boston on November 16 next.

CONTINUATION OF EXPERIMENTS ON ELECTRIC PROPERTIES OF URANIUM.[1]

IN a paper read before the Society on March 1, we had the honour to communicate some preliminary results on the electric properties of uranium. We propose now to give other results on the same subject, bearing on the conductance induced in air by uranium.

To measure the leakage in air at ordinary pressure at different voltages, we used in our first experiments the two-Leydens method described in a former paper. We found that the leakage was not proportional to the electro-motive force. It was not perceptibly increased when the uranium was heated, or when the sunlight fell on it.

We also observed the leakage in hydrogen, oxygen, and carbonic acid. The experimental arrangements necessary for this are described in a paper published by the Royal Society of Edinburgh. We found that the rate of leakage is greater in oxygen than in air. The ratio of the rates depends on the voltage chosen. The leakage in hydrogen is less than in air. In carbonic acid it is less for four volts per two cms., but greater for ninety volts per two cms. than it is in air; for the latter voltage the leakage in carbonic acid is greater even than the corresponding leakage for oxygen at ordinary pressure. We also made experiments with air, hydrogen, oxygen, and carbonic acid at different atmospheric pressures. We found that the leakage in air at pressures ranging from 760 mms. to 23 mms. was very nearly proportional to the atmospheric pressure. The rate of leakage for lower pressures was so slow as to make the results not very trustworthy. At pressures under 2 cms. no appreciable leakage with 4 or with 90 volts per two cms. was observed. With hydrogen, oxygen, and carbonic acid the rate of leakage at higher pressures was somewhat approximately proportional to the pressure, at lower ones to the square root of the pressure.

We found that at ordinary atmospheric pressure, sparking took place in air at 4800 volts, between a rough fragment of uranium and a metal tube around it, connected to the two electrodes of a vacuum-tube within which they were fixed. At 232 mms. pressure, the potential necessary to produce a spark fell to between 1500 and 2000 volts. At 127 mms. it had fallen to between 1100 and 1300 volts. At 54 mms. it was 700 volts; at 7 mms. 420 volts; at 2 mms. about 400 volts. At 1/1000 mm. the voltage necessary to produce sparking rose again to 2000 volts.

To measure the potential difference between two mutually insulated metals when the air between them is rendered conductive by the presence of uranium, we used two methods, which are described more particularly in the paper above referred to. The steady reading obtained when the quadrants of an electrometer were in metallic connection we shall call the metallic-zero. The deviation from the metallic-zero, when the quadrants were insulated, to a steady point—the uranium-conductance-zero, as we shall call it—depended on the volta difference between the two opposed surfaces of metals, more or less tarnished as they generally were. This deviation took place gradually in about half a minute with one arrangement of apparatus, and in about four minutes with a second arrangement. On the other hand, if the insulated metal had a charge given to it of such an amount as to cause the electrometer reading to deviate from the metallic zero beyond the uranium-conductance-zero, the reading quickly fell to this conductance-zero, and there remained steady.

The following table gives the potential differences between the electrometer wires, when one of them is connected with uranium, and the other with a plate of one or other of the named metals opposed to it:—

[1] By Lord Kelvin, Dr. J. Carruthers Beattie, and Dr. M. S. de Smolan. Read before the Royal Society of Edinburgh, April 4.

Metal.	Volt.
Polished aluminium (1) immediately after being polished	– 1·13
Polished aluminium (1) next day	– 0·90
Polished aluminium (2)	– 1·00
Amalgamated zinc	– 0·80
Polished zinc	– 0·71
Unpolished zinc	– 0·55
Polished lead...	– 0·54
Tinfoil	– 0·49
Unpolished alumininum (1)	– 0·41
Polished copper	– 0·17
Silver coin	+ 0·05
Unpolished copper	+ 0·07
Carbon	+ 0·20
Oxidised copper (*a*)	+ 0·42
Oxidised copper (*b*)	+ 0·90

It will be noticed that the difference of potential observed depends very much on the state of polish of the metal concerned. With a third specimen of oxidised copper a potential difference of + 0·35 of a volt was obtained. This specimen was afterwards connected to sheaths; a piece of polished aluminium was placed opposite it, and connected to the insulated terminal of the electrometer. The uranium disc, insulated on paraffin, was then placed between them, and the deviation observed was equivalent to a potential difference of – 1·53 volts; that is, we obtained an effect equivalent to the sum of the effects we had when the metals were separately insulated in air opposite to uranium.

We observed also the effect of various screens on the rate of reaching the conductance-zero. For example, when a sheet of lead about 2 mms. in thickness was used as screen, no deviation from the metallic-zero was obtained. In other words, lead 2 mms. thick is not transparent to the uranium influence. Glass 3 mms. thick did not entirely stop the deviation; it reduced the deviation in the first minute, however, to $\frac{1}{4}$ of the amount obtained with no screen. A copper screen, 0·24 mm. in thickness, reduced the rate to $\frac{1}{3}$; two copper screens, total thickness 0·48 mm., reduced it to $\frac{1}{12}$; three copper screens, 0·72 mm., reduced it to $\frac{1}{40}$. A mica screen did not reduce the rate at all. A zinc screen, 0·235 mm. thick, reduced it to $\frac{1}{2}$. Two zinc screens, total thickness 0·47 mm., reduced it to $\frac{1}{7}$. Paraffin, 3 mms. thick, when placed between the two mutually insulated metals, stopped the deviation from the metallic to the conductance-zero.

The final difference of potential observed between the electrometer wires connected to two mutually insulated metals, when the air between them was made conductive by uranium, was found to be independent of the distance between the metals through distances ranging from less than $\frac{1}{2}$ cm. to 8 cms.

The difference of potential observed when two mutually insulated metals were brought into electric connection with one another by a drop of water, was in the same direction as the uranium conductance-zero between the two surfaces when dry, and was smaller in magnitude. On the other hand, when the uranium surface was covered with water to the depth of about a millimetre, and an air space left above the water, between the submerged uranium surface and the opposed insulated metal, so that we had uranium-water-air-metal, the rate of deviation from the metallic-zero was reduced so much as to be scarcely observable.

We found that the uranium-conductance-zero between zinc and uranium was the same in air, hydrogen, and oxygen. And that the final steady reading did not depend on the atmospheric pressure, though the rate at which this steady reading was reached did largely depend on the atmospheric pressure.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Dr. Nansen has made a contribution of £50 towards the teaching of Geography in the University.

The voting of the Senate on the resolutions respecting degrees for women will take place from 1 to 3 p.m. on Friday, May 21, in the Senate House.

The University of Madras is to be added to the list of Indian Universities which are affiliated to the University of Cambridge.

On account of the incidence of the Jubilee celebrations, the degree days at the end of this term are displaced to June 18 and 19.

THE Universities of Edinburgh and Glasgow each receive the sum of 5000*l*. by the will of the late Miss Brown, of Waterhaughs, Ayrshire. Miss C. Trow has left a bequest of 2000*l*. to found a scholarship, to be called the "Thomas Trow Scholarship," in St. Andrews University.

AT a recent meeting of the Governors of McGill University, it was resolved to institute forthwith a chair of Zoology in the University, the Chancellor, Sir Donald A. Smith, generously undertaking to defray the expenses of the foundation. With the sister department of Botany suitably equipped and provided for, it will be possible to make considerable advances along the lines of biological research and investigation.

THE *Lancet* states that at the statutory half-yearly meeting of the General Council of Edinburgh University, held last week, the draft ordinance issued by the Universities Commission instituting a "Professorship of Public Health and Sanitary Science (to be called the Bruce and John Usher chair of Public Health)" was approved. The professor of this new chair is to have a salary of not less than 600*l*. Mr. A. L. Bruce's bequest was "in acknowledgment of Pasteur's investigations."

THE March *Journal* of the South-Eastern Agricultural College, Wye, does credit to that young and vigorous institution, and to the County Councils of Kent and Surrey. Mr. F. V. Theobald contributes a number of instructive notes on injurious insects; and there are in the *Journal* several papers which should prove of great value to hop-growers, one, by Mr. John Percival, on the hourly temperatures of hops from the beginning to the completion of an oasting, being of special importance.

THE following are among recent appointments:—Dr. Beckenkamp to be professor of mineralogy at Würzburg; Prof. L. Claisen, of Aix, to be professor of chemistry at Kiel; Dr. Gaupp to be an assistant professor of anatomy in the University of Freiburg; Dr. E. H. Loomis, instructor of physics in Princeton University, to be assistant professor of physics in the same University; Dr. Friedrich Gräfe to be associate professor of mathematics in the Technical High School at Darmstadt; Dr. E. Fischer, associate professor of botany at Berne, to be professor and director of the botanical gardens in that place; Dr. P. Francotte to be professor of embryology at Brussels, and Dr. P. Stroobant to be professor of astronomy at the same place.

WE have received a copy of a memorandum drawn up by Dr. R. W. Stewart, principal of the Hartley Institution, Southampton, on behalf of the Hartley Council, and sent to the Chancellor of the Exchequer. The memorandum urges the claims of the Hartley Institution to a share of the increased grant which it is proposed to give to the University Colleges of Great Britain. That the Institution is doing valuable educational work must be acknowledged, but, judging from the memorandum, it attempts too much. We also venture to say that our University Colleges stand on a somewhat higher educational plane than the Hartley Institution, in spite of Dr. Stewart's reorganisation of the work, and the appointment of a "professional" staff. Certainly, if the application is considered, some of our best technical colleges will be justified in lodging a similar claim.

MR. J. PASSMORE EDWARDS' contributions to the streams which give life and strength to the physical and mental character of many sections of the community are so numerous, that they are almost past counting. We may be permitted to regret that but a minor rivulet having Mr. Passmore Edwards' generosity as a source flows through the field of scientific investigation, but at the same time we are glad that the growth and extension of education has been encouraged by a constant flow of gifts. How well Mr. Passmore Edwards has ministered to the general advancement of the people, may be seen from a recent publication containing illustrations of institutional buildings for educational and ameliorative purposes provided by him in response to public requests, and which will be completed or commenced during this year of the Jubilee. The buildings, twenty-five in all, constitute a most worthy contribution to the stream of individual and organised endeavour made during a notable year of a notable reign for the general good. Ten of the institutions illustrated are public libraries; two are public libraries and technical schools combined; and three will be devoted exclusively to artistic, scientific and industrial education; while all have been, or are being, built with funds provided by Mr. Passmore Edwards. When it is remembered that these do not include buildings of a similar character erected by the same donor before the commencement of the Diamond Jubilee year, a faint idea may be obtained of the valuable support he has given to educational agencies.

THE Report of the Council of the City and Guilds of London Institute upon the work of the Institute during 1896, may be taken as a complete reply to the few short-sighted people who, about this time last year, wished to see whether the results attained could be expressed in pounds, shillings and pence. In the Central College, and the Technical College, Finsbury, the Institute possesses establishments which show the way to improve technical education in this country. At the opening of the former College, the late Lord Selborne stated that "in the several laboratories with which this College is provided new and increased facilities will be afforded for the prosecution of original research, having for its object the more thorough training of the students, and the elucidation of the theory of industrial processes." As a supplement to the education which a student should receive at a college in the technical applications of science, Prof. W. E. Ayrton, the Dean of the College, points out that the experience which the student gains by carrying out a research is of great value in teaching him to think for himself, and acquire habits of self-reliance. Further, his having to adopt expedients for overcoming the experimental difficulties which are met with in all original researches trains his ingenuity, and this is necessarily of great value to one who is about to become an engineer, and who may, therefore, be brought face to face with totally new problems in practical life. The long list of investigations carried out in the various laboratories during the Sessions 1893-96, shows that this prosecution of original research has been carefully kept in view.—Dr. Sydney Williamson, who now holds the Salters' Company Research Fellowship at the College, has selected as his subject of investigation food stuffs generally, and more particularly some of the more definite albumenoids, with the ultimate object of ascertaining the influence of various manures on the growth of crops in so far as quality of produce is concerned. The subject is one of which we know practically nothing, and is obviously of great economic importance.

SCIENTIFIC SERIALS.

American Journal of Science, April.—Experimental investigation of the equilibrium of the forces acting in the flotation of discs and rings of metal; leading to measures of surface tension, by A. M. Mayer. The author describes a number of experiments on the flotation of clean ungreased wires on water. By observing the weight required to make them break through the water surface, a good value for the surface tension of water may be obtained. It is a mistake to suppose that a wire ring will not float unless it is greased. A ring of 1 mm. aluminium wire 5 cm. in diameter will make a depression of 5 mm. in a clean water surface, and requires 2·6 grams to make it break through. The value of the surface tension of water at 0° obtained by the author is 0·0809, which is $3\frac{1}{2}$ per cent. higher than the mean of all determinations hitherto made.—Note on computing diffusion, by G. F. Becker. Introduces a simplified method of treating diffusion of substances in solvents and of heat in rocks, for the use of geologists, together with skeleton tables for the rapid computation of diffusions.—The application of iodic acid to the analysis of iodides, by F. A. Gooch and C. F. Walker. Iodic acid is easily and completely reduced by an excess of hydriodic acid with the liberation of iodine according to the equation: $HIO_3 + 5HI = 6I + 3H_2O$. The authors work out a method for the quantitative estimation of iodides, dependent upon the action of iodic acid or an iodate in the presence of free sulphuric acid, neutralisation of the solution by means of an acid carbonate, and titration of the free iodine by arsenious acid, five-sixths of the iodine thus found being credited to the iodide to be estimated. In the absence of large amounts of chlorides or bromides, the method is simple, rapid, and fairly accurate.—Difference in the climate of the Greenland and American sides of Davis and Baffin's Bay, by R. S. Tarr. The climate of

Greenland is milder than that of Baffin's land, partly owing to a warm current which skirts the land northward as far as Melville Bay, and partly owing to a difference in the prevalent winds. Greenland is being depressed, probably owing to an accumulation of ice, which is now being taken off from the glaciers where they enter the sea. The American side is rising north of Labrador.—Temperature and ohmic resistance of gases during the oscillatory electric discharge, by J. Trowbridge and T. W. Richards. Although a vacuum tube will offer a resistance of several thousand ohms to a continuous discharge, its resistance to an oscillatory discharge may not exceed ten or twenty ohms, as shown by the feeble damping impressed upon the discharge. The latter is determined by spark photographs, and by finding what wire resistance will produce the same amount of damping.—Does a vacuum conduct electricity? by John Trowbridge. It does.—The affinities of Hesperornis, by O. C. Marsh. Points out that his characterisation of Hesperornis as a "swimming ostrich" in 1872, has since been verified (see NATURE, vol. lv. p. 534).

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 8.—"Double (Antidrome) Conduction in the Central Nervous System." By C. S. Sherrington, M.A., M.D., F.R.S., Holt Professor of Physiology, University College, Liverpool. Received Februaiy 15.

In a paper presented to the Society last year, I drew attention to the fact that if, after transection over the bulbospinal axis, the *funiculus gracilis* be excited, at the *calamus scriptorius*, the excitation evokes movement (contraction, relaxation) in the idiolateral hind limb. If instead of *f. gracilis* the *funiculus cuneatus* be excited, the movement (contraction, relaxation) is in the idiolateral fore limb. The movement in the hind limb is in the monkey usually adduction and flexion of hallux, in the cat flexion of knee, hip, or ankle. In the monkey the fore limb movement is usually flexion and adduction of pollex, often with extension of the other digits; in the cat, more usually flexion of elbow with protraction of the shoulder. The movements which occur are, however, various, and I will here only add that those from the *f. gracilis* include the vaginal and anal orifices, the tail, and the abdominal muscles, those from *f. cuneatus* the diaphragm; but that neither from *f. gracilis* nor *f. cuneatus* have I obtained idiolateral extension of elbow or of knee.

The reaction is obtainable when the transection has been made altogether below the *nuclei graciles et cuneati*. It therefore does not necessarily involve the cells of those nuclei.

The reaction from the left *f. gracilis* is annulled by severance of the left dorsal column, that of the right by the severance of the right.

What, then, is the nature of this reaction obtainable from the *f. graciles* and *cuneati*? The reaction is evidently one which involves each dorsal column of the cord as a conducting path, in many cases even employing its whole length. In light of the evidence given above, I infer that although certainly, as has been long established, the dorsal column is, with the single exception of its short, scanty, and deeply-placed ground-bundle, a functionally pure *upward* path, consisting of nothing else than sensory root fibres, the vast majority of which—and the entirety of the longest of which—are ascendant; the conduction along it in these experiments is *downward*, even extending its whole length. That is to say, the conduction must be downward and cellulipetal along ascending axons which function in a cellulifugal direction; that is to say, the propagation of the impulses artificially started in my observations must have been *antidrome* instead of *orthodrome*. The motor discharges evoked I refer to the spread of the excited condition into the collaterals of the axons excited to antidrome conduction, their collaterals impinging upon motor neurons.

The direction of propagation occurs therefore in opposition to the law of the "*polarisation dynamique des nevrons*" put forward by Ramon y-Cajal and V. Gehuchten. It offers, however, no contradiction to what James has termed "the law of forward direction"; it only emphasises that that law predicates the existence of at least two links in its conduction-gear.

The reaction is therefore, in my view, an extreme illustration of double (antidrome, *doppelsinnige*) nervous conduction. After du Bois' fundamental observation with frog's sciatic and the electrical sign, it has been Kühne's *sartorius* experiment, and Babuchin's reversed discharge in the electric organ nerve-fibre, which have laid a satisfactory foundation for double conduction in peripheral nerves. But between those experiments and these, the subject of this note, there are, it is true, differences. In the latter, (α) propagation occurs over relatively huge distances and (β) the reaction occurs within the field of the central nervous system. These differences need not, however, negative the relationship of the phenomena. They render it the more instructive.

It is obvious that there must be opportunity for detection of antidrome conduction in parts of the central nervous system besides the dorsal spinal columns. Thus, on exciting, especially with electric currents, the mammalian metencephalon (*vermis cerebelli*) and *isthmus rhombencephali*, subsequent to ablation of the parts above, I have seen movements produced in the limbs and trunk, and also inhibitions occur. Thus, in instance of the latter, inhibition of the tonic extensor spasm of the fore and hind limbs combined with contraction of the flexors of knee and elbow, such as is seen under local spinal reflex action. It will have to be determined whether in such cases as the former we have not before us instances of antidrome conduction along ascending paths. The antidrome phenomenon, while of valuable assistance when recognised, may, if unrecognised, give rise to very misleading inferences. Its methodic use should place in our hands a fresh instrument of value for neurological research.

"On the Breaking-up of Fat in the Alimentary Canal under Normal Circumstances and in the Absence of the Pancreas." By Vaughan Harley, M.D., M.R.C.P., Professor of Pathological Chemistry, University College, London. Received March 18.

In this paper the author, after stating the results of his previous experiments, in which he found that from 21 to 46 per cent. of the total fat given in a milk diet was absorbed from the alimentary canal in the space of seven hours in normal dogs, found that in those dogs in which the pancreas had been entirely removed two days previously, no evidence of any absorption could be obtained during the same time.

The fact that no marked absorption of fat occurred in dogs after the extirpation of the pancreas, seems to confirm the old view that the pancreatic secretion was necessary for absorption.

This alleged action of the pancreatic juice in preparing fat for its absorption, is usually supposed to be due to the fat-splitting ferment and the alkaline sodium carbonate, which combines to form soaps with the free fatty acids.

In the author's paper he investigated whether, after the removal of the pancreas, fat continued to be broken up in the alimentary canal. For this purpose animals were fed on milk, and seven hours later the contents of the stomach, small intestines, and large intestines were separately analysed with regard to the quantity of neutral fat, free fat acids, and fat acids as soaps.

As far as the stomach is concerned, the quantity of fat acids was increased in the dogs in which the pancreas had been removed. It seems that this increase is probably due not to a greater splitting-up action of the fat, but to the longer retention of the fat in the stomach; for after the pancreas is removed, the motility of the stomach is much diminished.

Soaps also were formed both in the normal and pathological dogs, so that both in the normal dogs as well as in those in which the pancreas had been removed, the stomach is capable not only of splitting up neutral fat into free fat acids and glycerine, but that, further, they are capable of finding an alkaline substance with which they can form soaps even in the acid stomach contents.

The power of the free fatty acids for forming soaps is, however, extremely limited in the stomach. In normal dogs the principal fat-splitting action really begins not in the stomach, but after it has left the pylorus.

The normal dogs contain no less than 72·22 per cent. of the total fat as free fat acids, while, when the pancreas had been entirely removed, no less than 61·62 per cent. of the total fat was thus present. There can be no doubt, therefore, that even where no pancreatic secretion has reached the intestines, a very considerable quantity of neutral fat is split up into free fat acids in the small intestine, although the quantity there formed is not

so great as when the pancreatic secretion has been able to share in the work.

The formation of soap is also carried on as in the normal dogs.

In the contents of the large intestine, the normal dogs, and those in which the pancreas had been previously removed, for all practical purposes showed an equal breaking-up of the neutral fat.

Linnean Society, April 15.—Dr. A. Günther, F.R.S., President, in the chair.—Mr. H. Fisher, the naturalist attached to the Jackson-Harmsworth Polar Expedition, gave some preliminary observations on the plants collected by him during his two years' residence in Franz-Josef Land.—On behalf of Mr. A. O. Walker, an abstract was read of a paper on some new Crustacea from the Irish Seas. Of the four species of Edriophthalma described as new, two of them, viz. *Leuconopsis ensifer* and *Stenothoë crassicornis*, were taken, at a depth of 33 and 23 fathoms respectively, during the dredging and trawling operations of the Liverpool Marine Biological Committee, in April 1896. Of the other two novelties, *Apseudes hibernicus* was taken by Mr. Gamble between tide-marks during a week's collecting at Valentia Harbour; and *Parapleustes latipes* was found by Mr. Walker, while naming the collection of Amphipoda in the Dublin Museum of Science and Art. Four specimens were taken in 750 fathoms off the south-west coast of Ireland.—The Secretary gave an abstract of a paper by Dr. A. J. Ewart, on the evolution of oxygen from coloured bacteria. The author found that coloured bacteria, under certain appropriate conditions, possess the power of evolving oxygen in greater or less amount. In some the oxygen appeared to be absorbed from the air by the pigment substance excreted by the bacteria. The process, he considered, was not a vital one. The substances contained in an alcoholic extract were found to have the same power, though less marked, of occluding oxygen; but this property was soon lost. The purple and green bacteria, in which the pigment forms an integral part of the bacterial plasma, when exposed to radiant energy showed a very weak evolution of oxygen, continuing for an indefinite period under favourable conditions. In the former of these the assimilatory "pigment" is "bacterio-purpurin," in the latter "chlorophyll." The process in this case is a vital one, and the oxygen evolved is apparently derived from the assimilation of carbon dioxide.

Zoological Society, April 29.—Sixty-eighth Anniversary Meeting.—In the absence of the President, the chair was taken by Dr. Edward Hamilton, Vice-President. After the auditors' report had been read and a vote of thanks accorded to them, and some other preliminary business had been transacted, the report of the Council on the proceedings of the Society during the past year was read by Dr. P. L. Sclater, F.R.S., the Secretary. The total receipts of the Society for 1896 had amounted to 27,081*l*. 10*s*. 4*d*. The ordinary expenditure in 1896 had amounted to 23,788*l*. 1*s*. 2*d*. Besides this, a sum of 2617*l*. 15*s*. had been paid and charged to extraordinary expenditure, of which amount 2600*l*. had been paid on account of the construction of the new house for ostriches and cranes. A further sum of 1000*l*. had also been transferred to the deposit account, leaving a balance of 1066*l*. 15*s*. 4*d*. to be carried forward for the benefit of the present year. The number of visitors to the Gardens in 1896 was 665,004. The number of animals in the Society's Gardens on December 31 last was 2473, of which 902 were mammals, 1132 birds, and 439 reptiles and batrachians. Amongst the additions made during the past year eighteen were specially commented upon as of remarkable interest, and in most cases new to the Society's collection. Amongst these were a young male manatee, from the Upper Amazons; a young male klipspringer, from North-east Africa; a young female gorilla, from French Congoland; a pair of lettered aracaris, from Pára; a young Brazza's monkey, from French Congoland; a Loder's gazelle, from the Western Desert of Egypt; three ivory gulls, from Spitzbergen; and three Franklin's gulls, from America. The report having been adopted, the meeting proceeded to elect the new members of Council and the officers for the ensuing year. The usual ballot having been taken, it was announced that William Bateson, F.R.S., Colonel John Biddulph, Dr. Albert Günther, F.R.S., Osbert Salvin, F.R.S., and Joseph Travers Smith had been elected into the Council in the place of the retiring members, and that Sir William H. Flower, K.C.B., F.R.S., had been re-elected President, Charles Drummond, Treasurer, and Dr. Philip Lutley Sclater, F.R.S., Secretary to the Society for the ensuing year.

PARIS.

Academy of Sciences, April 26.—M. A. Chatin in the chair.—On the Inseminеæ with two integuments, forming the subdivision of the Bitegmineæ, by M. Ph. van Tieghem.—Researches on the composition of wheat, and on its analyses, by M. Aimé Gerard. The chemical analysis should in all cases be preceded by a mechanical separation of the different parts of the grain, approximating to the process of milling, if the analysis is to be of any service to the baker. For baking purposes it is not sufficient to determine the total gluten only, but this must be supplemented by finding the ratio of glutenine to gliadine.—On the immunity of the fowl against human tuberculosis, by MM. Lannelongue and Achard. The effects produced on fowls and pigeons by inoculation with tubercle bacilli, appear to be the same whether the organisms are alive or dead. But although the bacilli appear to lose their power of spreading, they remain alive and virulent in the local lesion, the blood of the fowl not containing any substance capable of destroying, or even interfering with the growth of the bacilli.—Influence of surfusion on the freezing point of solutions of sodium chloride and alcohol, by M. Raoult. The relation between the true lowering of the freezing point, C, the observed lowering, C^1, and the surfusion, S, is given by $C = C^1 (1 - KS)$, where K is a constant. It follows that for the same surfusion, with the same instrument and method of working, the ratio C/C^1 is constant, and that the error due to surfusion is without effect upon the meaning of the results. Experiments are given for aqueous solutions of sodium chloride and of alcohol, six concentrations of each. The results are in accordance with the theory of Arrhénius.—Monograph of the quaternary fossils of Algeria, by M. A. Pomel.—Memoir on a method for the rapid determination of distances, by M. N. Ursalovitch.—On the theory of flying, by M. Chantron.—Remarks by M. Bouquet de la Grye on presenting the results of the triangulation of Corsica.—On the electric properties of the radiations emitted by bodies under the influence of light, by M. Gustave Le Bon. Some experiments are quoted, which show that the criticism of previous results, based upon the supposed transparency of the ebonite plate used, was unfounded. Substances under the action of light emit rays which cause the discharge of electrified bodies, the rapidity of discharge varying with the nature of the substance. This action has already been shown for uranium by M. Becquerel, which appears to be only a particular case of a general law.—The thermoluminescence caused by the rays of M. Röntgen and M. Becquerel, by M. J. J. Borgman.—On the biphosphide of silver, by M. A. Granger. Reduced silver kept in an atmosphere of phosphorus at 400° is slowly transformed into a definite phosphide, AgP_2, which is decomposed again at 500°, so that silver, like gold, presents the peculiarity of absorbing phosphorus at 400°, giving it up again at 500°, and retaining it again at 900°.—On nitrosomethyl-diphenylamine, by M. Ch. Cloëz. All attempts to prepare a dinitrosomethyl-diphenylamine were fruitless, the mono-nitroso-derivative being always obtained. The amine being a very feeble base, for a good yield an excess of concentrated hydrochloric acid is necessary, and the mixture must be well cooled.—New Coccidia in the digestive canal of Myriapods, by M. Louis Leger. One of these is found in the digestive tube of *Lithobius impressus*, where it is so numerous that during six days the excrements were almost entirely composed of hundreds of cysts of this Coccidium. It appears to be allied to the genus *Barroussia* (A. Schneider), but is clearly distinguished from the *B. ornata* of Nèpe, by the form of the cyst and spores. The second is found in several species of *Lithobius*, especially *L. castaneus*, *L. forcipatus*, and *L. Martini*, and is identical with the genus *Bananella* of M. Labbé.—On a supposed disease of truffles caused by worms, by M. Joannes Chatin. The worms observed in truffles are simple saprophytes, offering no danger to man.—On the nutritive apparatus of *Cladochytrium pulposum*, by M. Paul Vuillemin. The nutritive apparatus of this parasite is a naked granular protoplasmic mass, containing numerous rings and bundles of striated muscular fibrillæ. It acts upon the cellulose membranes.—The radical cure of hernia by injections of chloride of zinc, by M. Demars. A description of six cases, all of which were cured, apparently permanently, by the above method.—

Note on the preceding communication, by M. Lannelongue.—On the locomotive action of the anterior members of the horse, by M. P. Le Hello. As a result of the photographic study of the horse in motion, mechanical apparatus has been constructed demonstrating the muscular actions.—The action of the sun and the moon upon the atmosphere, and on the anomalies of the pressure, by M. P. Garrigou-Lagrange.

DIARY OF SOCIETIES.

THURSDAY, MAY 6.

ROYAL INSTITUTION, at 3.—Liquid Air as an Agent of Research: Prof. J. Dewar, F.R.S.

SOCIETY OF ARTS, at 4.30.—Kafiristan: its Manners and Customs: Sir George Scott Robertson, K.C.S.I.

LINNEAN SOCIETY, at 8.—On Desmids from Singapore: W. and G. S. West.—The Problem of Utility: Captain W. F. Hutton, F.R.S.—On New Species of Mollusca from the Island of Madeira: Rev. R. Boog Watson.

CHEMICAL SOCIETY, at 8.—A Bunsen Burner for Acetylene: A. E. Munby.—On the Reactions between Lead and the Oxides of Sulphur: H. C. Jenkins and A. E. Smith.—Ballot for Election of Fellows.

GRESHAM COLLEGE (Basinghall Street), at 6.—Planets Saturn, Uranus, and Neptune: Rev. Edmund Ledger.

FRIDAY, MAY 7.

INSTITUTION OF MECHANICAL ENGINEERS, at 7.30.—Experiments on Propeller Ventilating Fans, and on the Electric Motor driving them: William G. Walker.

GEOLOGISTS' ASSOCIATION, at 8.—Coral Islands: W. W. Watts.

GRESHAM COLLEGE (Basinghall Street), at 6.—Planets Saturn, Uranus, and Neptune: Rev. Edmund Ledger.

SATURDAY, MAY 8.

ROYAL BOTANIC SOCIETY, at 4.

GEOLOGISTS' ASSOCIATION—Excursion to Southborough and Tunbridge Wells. Director: G. Abbott. Leave Charing Cross Station (S.E.R.) 9.22 a.m.; arrive Southborough 10.50 a.m.

LONDON GEOLOGICAL FIELD CLASS.—Excursion to Caterham to Redhill, *viâ* Godstone. Upper Greensand. Leave Cannon Street 2.17; arrive Caterham 3.12.

MONDAY, MAY 10.

SOCIETY OF ARTS, at 8.—Design in Lettering: Lewis Foreman Day.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Recent Journeys in Sze-Chuan, Western China: Mrs. Bishop.

TUESDAY, MAY 11.

ROYAL INSTITUTION, at 3.—Volcanoes: Dr. Tempest Anderson.

ROYAL HORTICULTURAL SOCIETY, at 1.—Diseases of Plants.

ANTHROPOLOGICAL INSTITUTE, at 8.30.—A Lantern Demonstration on the Anthropological Features of the External Ear: Dr. A. Keith.—*Probable* Papers: A Quinary System of Notation used in Luchoo: Prof. Basil Hall Chamberlain.—Ancient Measures in Prehistoric Monuments: A. L. Lewis.—Rock Paintings and Carvings of Australian Aborigines: R. H. Mathews.

IRON AND STEEL INSTITUTE, at 10.30.—Annual Meeting.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—Portraiture: Harold Baker.—Mr. Rogers, of Watford, will show his Acetylene Burner for Portraiture.

ROYAL VICTORIA HALL, at 8.30.—More about Röntgen and other Rays: Prof. A. W. Porter.

WEDNESDAY, MAY 12.

SOCIETY OF ARTS, at 8.—Motor Traffic: Technic Considerations: Sir David Salomons, Bart.

GEOLOGICAL SOCIETY, at 8.—The Gravels and Associated Deposits at Newbury (Berks): E. P. Richards.—The Mollusca of the Chalk Rock, Part II.: Henry Woods.

IRON AND STEEL INSTITUTE, at 10.30 a.m.—Annual Meeting.

THURSDAY, MAY 13.

ROYAL SOCIETY, at 4.30.—*Probable* Papers: An Attempt to cause Helium or Argon to pass through Red-hot Palladium, Platinum, or Iron: Prof. Ramsay, F.R.S., and M. W. Travers.—On the Negative After-Images following Brief Retinal Excitation: Shelford Bidwell, F.R.S.—A Dynamical Theory of the Electric and Luminiferous Medium. Part III. Relations with Material Media: Dr. J. Larmor, F.R.S.—On a New Method of Determining the Vapour Pressures of Solutions: E. B. H. Wade.—On the Passage of Heat between Metal Surfaces and Liquids in Contact with them: T. E. Stanton.—On the Magnetisation Limit of Wrought Iron: H. Wilde, F.R.S.

ROYAL INSTITUTION, at 3.—Liquid Air as an Agent of Research: Prof. J. Dewar, F.R.S.

MATHEMATICAL SOCIETY, at 8.—On Cubic Curves as connected with certain Triangles in Perspective: S. Roberts, F.R.S.—An Analogue of Anharmonic Ratio: J. Brill.—An Essay on the Geometrical Calculus (Continuation): E. Lasker.—On the Partition of Numbers: G. B. Mathews.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—The Generation of Electrical Energy for Tramways: J. S. Raworth. (Discussion.)—Disturbances of Submarine Cable Working by Electric Tramways: A. P. Trotter.

FRIDAY, MAY 14.

ROYAL INSTITUTION, at 9.—Explosion-Flames: Prof. Harold Dixon, F.R.S.

ROYAL ASTRONOMICAL SOCIETY, at 8.

PHYSICAL SOCIETY, at 5.

MALACOLOGICAL SOCIETY, at 8.

SATURDAY, MAY 15.

GEOLOGISTS' ASSOCIATION.—Excursion to Chislehurst. Directors: W. Whitaker, F.R.S., and T. V. Holmes. Leave Charing Cross (S.E.R.) at 1.35; arrive at Chislehurst 2.19.

LONDON GEOLOGICAL FIELD CLASS.—Excursion from Snodland to Aylesford, to view the Gault. Leave Cannon Street 2.37.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—A Treatise on Rocks, Rock-Weathering, and Soils: G. P. Merrill (Macmillan).—Birds of our Islands: F. A. Fulcher (Melrose).—A Plea for the Unborn: H. Smith (Watts).—Through a Pocket Lens: H. Scherren (R. T. S.).—Researches on the Evolution of the Stellar Systems: Dr. T. J. J. See, Vol. 1 (Lynn, Mass., Nichols).—A Course of Practical Histology: Prof. E. A. Schäfer, 2nd edition (Smith, Elder).—Dynamic Sociology: L. F. Ward, 2 Vols., 2nd edition (New York, Appleton).—A Handbook to the Birds of Great Britain: Dr. R. B. Sharpe, Vol. iv. (Allen). Papers and Notes on the Genesis and Matrix of the Diamond: Prof. H. C. Lewis (Longmans).—The North-Western Provinces of India: W. Crooke (Methuen).—Grundriss der Entwicklungsgeschichte des Menschen und der Säugethiere: Dr. O. Schultze, Zweite Hälfte (Leipzig, Engelmann).—First Stage Physiography: A. M. Davies (Clive).

PAMPHLETS.—Le Climat de la Belgique, 1896: A. Lancaster (Bruxelles). Réunion du Comité International Permanent pour l'Exécution de la Carte Photographique du Ciel, Mai 1896 (Paris, Gauthier-Villars).—A Study in Insect Parasitism: L. O. Howard (Washington).—Philosophical Transactions of the Royal Society of London: On the Capacity and Residual Charge of Dielectrics as affected by Temperature and Time: J. Hopkinson and E. Wilson (Dulau).—A Summary of Progress in Petrography in 1896: W. S. Bayley (Waterville, Me.).—Hermann von Helmholtz: Gedächtnissrede von Emil du Bois-Reymond (Leipzig, Veit).

SERIALS.—Chambers's Journal, May (Chambers).—History of Mankind: F. Ratzel, translated, Part 18 (Macmillan).—Journal of the Chemical Society, April (Gurney).—Century Magazine, May (Macmillan).—Bulletin of the American Museum of Natural History, Vol. 8 (New York).—Proceedings and Transactions of the Nova Scotian Institute of Science, Session 1895–6 (Halifax, N.S.).—Proceedings of the American Association, Buffalo, N.Y., August 1896 (Salem).—Report of the International Meteorological Congress held at Chicago, August 21–24, 1893, Part 3 (Washington).—Contemporary Review, May (Isbister).—National Review, May (Arnold).—Journal of the Essex Technical Laboratories, Vol. 2 (Chelmsford).—The Humanitarian, May (Hutchinson).—Quarterly Journal of Microscopical Science, April (Churchill).—Proceedings of the Royal Society of Victoria, Vol. ix., new series (Melbourne).—Himmel und Erde, April (Berlin),

BOOKS ON BIRDS.

Life-Histories of North American Birds, from the Parrots to the Grackles, with special reference to their Breeding Habits and Eggs. By Charles Bendire, Captain and Brevet-Major, U.S.A. (retired). 4to, pp. ix + 518; with seven lithographic plates. Smithsonian Institution. United States National Museum. Special Bulletin. (Washington: Government Printing Office, 1895.)

Feathered Friends: Old and New. By Dr. W. T. Greene, M.A., &c. 8vo, pp. 302. (London: L. Upcott Gill, 1896.)

Coloured Figures of the Eggs of British Birds, with Descriptive Notices. By Henry Seebohm, author of "Siberia in Europe," &c. Edited (after the author's death) by R. Bowdler Sharpe, LL.D., &c., Assistant Keeper, Sub-Department of Vertebrata, British Museum. Pp. xxiv + 304. (Sheffield: Pawson and Brailsford, 1896.)

A Handbook to the Game-Birds. By W. R. Ogilvie-Grant, Zoological Department, British Museum. Vol. ii. Pheasants (continued), Megapodes, Curassows, Hoatzins, Bustard-Quails. (Allen's Naturalist's Library. Edited by R. Bowdler Sharpe, LL.D., F.L.S.) Pp. xvi + 316. (London: W. H. Allen and Co., Ltd., 1897.)

Among British Birds in their Nesting Haunts, illustrated by the Camera. By Oswin A. J. Lee. Parts 1 to 3. (Edinburgh: David Douglas.)

THIS volume of the life-histories of North-American birds, the third of the series of Special Bulletins issued by the Smithsonian Institution for the illustration of its collections deposited in the United States National Museum, is the second devoted to the land birds of the United States, and is from the same pen as its predecessor, the well-known Curator of Oology in that Museum, Captain Bendire. It is with very deep regret that we observe the recent announcement that death has snatched from his hands the completion of the task for which he was so competent by his untiring observations of many years, and in which he took the deepest interest.

The present volume treats of the parrots, cuckoos, trogons, kingfishers, woodpeckers, goat-suckers, swifts, humming-birds, cotingas, tyrant-flycatchers, larks, crows, starlings, and *Icteridæ*, the classification of the Code and Check-list of the American Ornithologists' Union being followed, as in Captain Bendire's first volume. He monographs 197 species, and especially discusses the range of the birds, their breeding habits, dates of nesting, and the description of their eggs. The latter are illustrated by natural-sized chromolithographs of 110 species on seven plates, nearly all of them executed with great fidelity to nature.

The life-history of each species is full and accurate, while many of the facts given are recorded for the first time as the result of Captain Bendire's own observations in many parts of America. He has laid under contribution those, also, of his numerous personal correspondents and of his brother ornithologists throughout the States. The outcome of the whole is a solid contribution to our knowledge of the families discussed. The plates, as already said, are excellent, and the text is beautifully printed on rich, smooth paper, in the sumptuous style of the Smithsonian Committee, who, having decided that a work is worthy to be published by them, spare no cost in worthily sending it forth to the world.

Dr. Greene's book, "Feathered Friends," contains, apparently, a reprint of articles contributed elsewhere. The "Friends" noticed are exclusively cage birds; and the information about them, which might have been condensed with advantage by the omission of many of the puerile stories of the Joey and Cat adventure type, contains, no doubt, some hints useful to those who keep birds in captivity, for whom, indeed, the volume is apparently intended. The woodcuts, which illustrate some of the species described, are not of the highest style of art or reproduction.

Henry Seebohm's "Coloured Figures of the Eggs of British Birds" is, to all intents, a new edition of the fourth volume, the plates, of his British birds, with the addition of the descriptions of their nests and eggs copied from that work, with a condensed account of the distribution of each species, its laying time and breeding places. The author's lamented death before its completion necessitated the bringing out of his book under the editorship of his friend Dr. Sharpe, who has done his best to present it as he believed Mr. Seebohm would have wished it to be issued. The book, as now published, is very complete, and for the oologist is quite independent of the large four-volume "British Birds." This handsome and somewhat bulky volume contains sixty plates with the figures of the eggs of 377 species of birds, and where the eggs are subject to variation, a series of the more characteristic deviations from the normal type has also been represented. We are safe from contradiction in saying that no work on British oology has been produced in this country in which the eggs have been so faithfully and artistically reproduced; as an example, we may refer to those of the kestrels and the guillemots on Plates 4 and 55 respectively. The book will, undoubtedly, remain the standard authority on the eggs of British birds for many years to come.

Dr. Sharpe has prefaced the work with an interesting and appreciative "personal reminiscence" of the author, in which Seebohm's chief contributions—and they are numerous and important—to ornithology, are summarised, and some of his many generous gifts to the National Collection, of which he was a constant benefactor, are rather indicated than fully detailed. A specially successful photogravure likeness of Mr. Seebohm forms a fitting frontispiece to the volume. It ought to be mentioned that the chromolithographic plates are the work of Messrs. Pawson and Brailsford, of Sheffield, and they prove that the highest class of chromolithography can be done as well in England as anywhere on the continent.

The second volume of Mr. Ogilvie-Grant's "Game-Birds" forms the latest addition to Allen's Naturalist's Library. His previous volume showed him to be a most accurate and conscientious worker, and that now under review will sustain his reputation in these respects. The British Museum is fortunate in possessing one of the most complete collections of game-birds in the world, only eighteen species of those known to science being

unrepresented in it. Mr. Grant has, consequently, in preparing his two volumes, had the opportunity, of which he has with infinite pains availed himself, of comparing his descriptions with the specimens in the National Collection. It is not too much to affirm that, as a guide to this group of birds, these two volumes have no superior, and though condensed, all the essential facts of their life-histories, so far as known, are carefully set out. As the editor justly remarks, they constitute "a small monograph of the *Gallinæ*." Two species are described in this volume as new, namely *Turnix whiteheadi*, one of that excellent naturalist's numerous discoveries in the Philippines, and *Ammoperdix cholmleyi* from the Soudan.

We have had more than once to note the unsatisfactory character of the plates in Allen's Naturalist's Library. There is, however, a slight improvement in this respect in the eighteen illustrations in the present volume, as compared with those of several of its predecessors; but as bird portraits they are still far from what they ought to be, especially in a work where the standard of the text is so high. Considerable carelessness is seen in Plate xxxiv., for instance, where the colouration differs widely from the description, the result of the cheap way in which the chromolithography has been executed. The poorness of the plates, however, cannot seriously interfere with the value and usefulness of this excellent handbook.

Mr. Oswin Lee presents us with still another work on British birds! Believing that among the number of books which have been published on British birds and their eggs, many of which are beautifully illustrated, there has never been published, so far as he is aware, any complete work giving faithful representations of their nests, he essays to supply the need by issuing to subscribers, at intervals of four to six weeks, a fascicle of photographs, which he hopes "will possess the accuracy of a scientific work on the nesting habits of birds, and yet be sufficiently attractive for the ordinary lover of birds." As to the excellence of the photographs as pictures, and of the general "get-up" of the work, as judged by the portions so far issued, we can speak with unqualified praise; that the latter, indeed, should be all that can be desired, goes without saying when we mention that the publisher is Mr. David Douglas, of Edinburgh. The plates are the *raison d'être* of the book, but each illustration is accompanied by "short descriptions of the habits of the birds at the nests, the finding of them, the materials of which they are formed, and the methods employed in getting faithful photographs of those more difficult of access, some of which . . . were only secured after hours of anxious watching and much patience." The difficulties to be overcome, and the patience required to secure a satisfactory plate of a bird on or by its nest, in a natural attitude, are, we admit, very great; but we think that in many cases the results are far from commensurate with the time, trouble, and expense devoted to securing them. We have more than once expressed in these pages the opinion that, with regard to the majority of nests, a photograph, taken close enough to give the details of the materials of which they are composed, and the form and markings of the eggs, must fail to convey a true idea of their site, size, or surroundings. Take, for instance, the nests of the *Vanellus vulgaris*. No one looking at Plate i. would, without explanation, recognise it as a lapwing's nest, for it appears as if composed of large twigs placed amid strong brushwood, the photograph having been taken at close quarters, and there being no object in the picture to suggest the dimensions of the eggs and grass relatively to the area occupied. Again, that on Plate ii., instead of giving one the impression of being on a ploughed field, as is intended, seems to be built in a nook in the face of a precipitous cliff! On the other hand, the illustration of the cormorant's nest is most charming. Here we have the nest and its eggs in the foreground of a little bit of scenery which forms a true scale for our mental picture. Photographs fail, we think, too, in suggesting the texture, character, and markings of the eggs. These are faults inherent to all camera pictures. Mr. Oswin Lee's photographs are, however, the best we have seen; and his notes, if short and containing, as a rule, few new observations, are generally his own, and are interesting and accurate. The small etched tail-pieces, from his own pencil, are delightful, and often catch with great fidelity some characteristic attitude of the birds he has been describing.

GEGENBAUR'S FESTSCHRIFT.

Festschrift zum Siebenzigsten Geburtstage. Von Carl Gegenbaur. Vols. i., ii. and iii. Pp. 436, 486, and 788. (Leipzig: Engelmann, 1896.)

THE three large volumes of essays and researches by the friends and pupils of Gegenbaur, form a very remarkable monument to the influence which the great Heidelberg Professor has exercised in the world of science.

The list of distinguished zoologists who contribute to the "Festschrift" would alone attract attention, and render the book worthy of a place in every zoological library; but the impression given on reading it, is that every one of the contributors has given his best work to the volume which does honour to the great master.

To fairly criticise the several essays, or even to notice the principal discoveries and conclusions made by the different authors, would almost mean a review of modern zoological research, for the contributions deal with a great variety of zoological problems and classes of animals.

It is true that the majority of Gegenbaur's pupils have written on subjects of vertebrate anatomy; but the essays on invertebrate morphology are none the less interesting and important.

The first, and in many ways the most striking, memoir is the one by Haeckel, on the Amphoridea and Cystoidea. All through the descriptions of genera and species, which form the greater part of the essay, the reader must feel the genius of Haeckel's extraordinarily powerful and fertile mind.

Many cautious palæontologists may complain that there is too much imagination about the work; that there is little proof that the restorations represent, even approximately, the form that these extinct animals possessed. But there is not really much difficulty in distinguishing between what is recorded fact and what is not, and the real gain to science in such a memoir is that we have a clear and concise picture given to us, in words and illustrations, of the thoughts about a group

of fossils by one who has thoroughly studied them, and can boldly write down his views.

The memoir will, doubtless, be severely criticised; but it is a notable piece of work, and one which all zoologists may read with advantage.

The first part of Richard Hertwig's memoir, on the development of the unfertilised egg of the sea-urchin, deals almost entirely with the phenomena of nuclear structure and division, and the influence upon them of strychnine and other reagents. The second part of "General Considerations" is an elaborate and exceedingly clever essay on nuclear structure and sexual differentiation.

One of the most important conclusions arrived at, is that the centrosome is a body derived from the nucleus, which passes into the protoplasm of the cell in order to bring into more intimate connection the nucleoplasm and cytoplasm during the process of cell-division.

He points out that, in such cases as Actinosphærium and other Protozoa, and in the formation of the polar bodies of Asteracanthion, where centrosomes are not apparent, there is very slight connection between nuclear division and division of the surrounding protoplasm.

The argument is not convincing, and, as Farmer has recently shown, must be considerably strengthened from the botanical side, at least, before the theory can be accepted.

G. von Koch's essay, on the skeleton of the stony corals, is important and interesting; but it will not attract so much attention as it might have done, had not Miss Ogilvie's memoir, recently published by the Royal Society, been more elaborate and, many will think, better.

Of the memoirs dealing with the anatomy and development of Vertebrata, the one by Hubrecht, on the development of Tarsius, is the most noteworthy. Although the essay is compressed into only thirty pages, and illustrated by but one plate and fifteen figures in the text, it may be regarded as a summary of the most important results of this distinguished embryologist's work.

It is quite certain that the peculiar features of the early development and placentation of the Spectral Lemur could have been rightly interpreted only by one who had worked previously at such mammals as the Insectivora. The extremely important resemblance which the Tarsius embryo at a certain stage presents to the human embryo, at what is probably a corresponding stage, is pointed out by Prof. Hubrecht, and the general features are illustrated by a plate of interesting and instructive diagrammatic figures.

But the memoir is not only strictly embryological; it deals with the zoological position of Tarsius from other points of view, and the conclusions are arrived at, firstly, that Tarsius is, as regards its dentition, intermediate between the Primates and the Mesozoic Insectivora, and secondly, that Cope's genus Anaptomorphus is intermediate between Tarsius and Man.

Of the other memoirs on Vertebrata, two seem to stand out prominently as of more than usual interest and importance. These are the essay, by Klaatsch, on the application of Gegenbaur's famous Archipterygium theory to the question of the origin of the pentadactyle limb, and Rosenberg's memoir on the vertebral column of *Myrmecophaga jubata*.

The former places before the student a clearly-expressed and carefully-considered theory, and is illustrated by numerous really admirable figures. Rosenberg describes some variations he has met with in the vertebral column of Myrmecophaga, and discusses fully the vexed question of the homologies of the Vertebræ in the Mammalia.

Other contributions to this work have been made by Boas, Oscar Hertwig, Corning, von Davidoff, Solger, van Bemmelen, Scott, Seydel, Maurer and Göppert; and it is not faint praise to say that they are well worthy of a place in these volumes.

Since the above was written, the third volume of this gigantic "Festschrift" has been forwarded to us. It is even larger and more profusely illustrated than the first two volumes, and is entirely devoted to questions of vertebrate anatomy. Four of the seven memoirs are concerned with the cranial and spinal nerves. Goronowitsch confines his attention to the Trigemino-facialis complex of Lota, and Haller to the Vagus group of the bony fish, the two essays taking the modest share of one hundred pages.

Unfortunately, perhaps, G. Ruge, who writes on the facial nerve of vertebrates, and Fürbringer on the spino-occipital nerves of the cartilaginous fish, have been unable to confine their contributions within these limits. To attempt to criticise the 600 pages which they take, would mean an attempt to criticise an encyclopædia of vertebrate knowledge. The student, however, will find in them a mass of solid facts which have important bearings on many important questions that are much discussed in these days. Fürbringer's memoir in particular, although overpowering in its size, has many passages which summarise, in a clear and masterly manner, questions of the homologies of nerves, and in this respect, at any rate, will form a most useful work of reference for anatomists.

Of the remaining three monographs the most important appears to be the one by Semon, on the excretory system of the Myxinoids. As in the earlier works of this distinguished anatomist, the reconstruction figures he gives are admirable.

Max Weber's interesting essay on the brain weight of Mammals, and Leche's researches on the teeth of recent and fossil Lemurs, are important contributions to knowledge; and although much shorter than others in this volume, are not the less valuable indices of the character of the work that has been produced by the pupils of Carl Gegenbaur.

THE DREARY DESERT OF NORTH TIBET.

Works of the Tibet Expedition of the Years 1889–1890, *under M. V. Pyevtsoff*; Part iii. 4to, pp. 127; with six maps. Published by the Russian Geographical Society. (Russian.) (St. Petersburg, 1896.)

THIS third part of the excellent publication issued by the Russian Geographical Society, contains the records of the incursions of Roborovsky and Kozloff into the border-ridges of the great Tibet plateau. While the main body of the expedition followed the northern foot of the Astyn-tagh border-ridge (or the "Russian Moun-

tains"), *viâ* the oases Niya and Cherchen, to lake Lob-nor, Roborovsky and Kozloff, with two or three men, pushed into the mountains, and beyond, into the wildernesses of the northern part of the Tibet plateau. These excursions, which were made under great difficulties, and in one of which Roborovsky's party was very nearly lost, are described in the present part of the "Works" of the expedition, and illustrated by six maps on the scale of 13 miles to an inch. The most important of these reconnoitring expeditions was the second, made by Roborovsky, when he crossed the Astyn-tagh, and, following a valley at its south-eastern foot, between the Astyn-tagh and the steep snow-covered Uzu-tagh, reached the Keria river, as it issues from the Tibet plateau and turns north-westwards, fringing the mighty glacier-covered Kuen-lun. No inhabitant of Kashgaria ever went that way, and nobody ever came to Kashgaria from that quarter; only a few gold-diggers visit the above-mentioned valley, without ever daring to penetrate further south into the dreary wilderness of the high plateau. Roborovosky did so, notwithstanding the terrible snow-storms, one of which, on May 22, covered the ground with three inches of snow. After having reached the Keria river, which flows at an altitude of 14,300 feet, and must be a mighty stream in summer, Roborovsky returned; but he came once more to the same spot, a couple of weeks later, moved by the desire of crossing the Uzu-tagh and of casting a glimpse on the dreary desert in the south of it. The altitude of the desert was 16,600 feet, and on June 12–14 almost no signs of life were found on it. Its surface is covered with low rows of stony hillocks, consisting of sharp-edged broken strata of quartzite, running west and east. A few bushes of a willow were found after a 22 miles' march, but no lichens were seen; and the only animals noticed were a few broken-down *orongo*-antelopes, which slowly walked within a few yards from the party—too weary to pay attention to it. Only snow seems to fall all the year round in this desert, and rain must be quite unknown. In June, snow fell every day, and evaporated immediately. On June 15 the altitude was 17,080 feet, and the temperature $-12°$ Celsius in the morning. The horses were severely suffering from the sharp stones, and broke down; so that the party was compelled to return, after having covered only 40 miles southwards. The desert stretched further south, as far as the foot of the snow-covered Kuen-lun. The return journey was extremely difficult, one horse only being able to stand it; and it was in a desperate condition that Roborovsky's party reached a spot where they had left some of their provisions.

The sand-storms in that part of Kashgaria, at the foot of the mountains, are simply terrible. The loess-terrace, which fringes the highlands, is easily destroyed by the wind, and the dust is carried in the air, becoming occasionally so dense that complete darkness prevails —nothing being seen at a distance of some ten yards. If it rains during such a dust-storm, the drops of rain evaporate as they fall, and the dust they carry with them falls in the shape of small lumps. Whole forests of poplars are buried in the loess-dust hillocks, forty feet high being blown round the trees, which soon die and slowly decay, after the wind has carried the hillock away, to spread the dust further on.

Another excursion into the highlands, during which nearly 500 miles were covered and mapped, was made to lakes Achik-kul, Chom-kum-kul, and "Unfreezing"—a salt lake at an altitude of 13,300 feet, which has various species of *Gammarus* among its fauna—and to Prjevalsky's Ridge, which is a mighty chain of mountains, buried in snow, running west and east under a number of local names, and very rich in animal life in its northern spurs.

A fourth excursion was made along the Cherchen-daria, which flows in a flat-bottomed valley, and has on both its sides two strips of sands, arranged by the wind in the shape of *barkhans* (rows of hillocks), attaining the extraordinary height of 360 feet. Great numbers of wild camels, stags, antelopes, wild cats, boars, and masses of small rodents and spiders, belonging to a variety of species, inhabit these sands, while the banks of the river are covered with poplars, tamarisks, and rushes. Traces of recent desiccation are found everywhere, and immense spaces are occupied with marshes, now covered with rushes, and strewn up with masses of fresh-water molluscs —the former inhabitants of a great lake. The population of the Lob-nor depression consists of half-breeds between Aryans and Turco-Mongols, who live in huts made of rushes, keeping some cattle, and carrying on fishing to a great extent.

The accounts of Roborovsky's and Kozloff's excursions to lake Bagrach-kul, near Karashar, and Kozloff's, up the Konche-daria, are also full of interest, and, like the preceding, give a good idea of the physical characters, flora and fauna, of the visited regions. General Pyevtsoff's discussion of Roborovsky's altitudes and astronomical observations completes this very interesting volume.

P. K.

OUR BOOK SHELF.

Algebra for Beginners. By T. Todhunter. New edition, revised and enlarged by S. L. Loney. Pp. xxxvi + 428. (London: Macmillan and Co., Ltd., 1897.)

THIS excellent elementary treatise is too well known to require detailed description in these columns, so we need only refer to the changes which have been made by the reviser of the new and enlarged edition. Prof. Loney has given additional chapters on negative quantities, the theory of quadratic equations, logarithms, and miscellaneous theorems, each of which has been inserted in those parts of the book which seemed most appropriate. The chapter on factors has been rewritten, and chapters towards the end have been considerably expanded. By renumbering the paragraphs, and maintaining the old numbers in smaller type, the reviser has facilitated the use of employing both editions together; the newly-added paragraphs contain only one—namely, the new—system of numbers. As examples form a very important part of such an elementary book as this, Prof. Loney has thought fit to more than double the original number, the answers being, as usual, included in the list at the end. Teachers will thus find in this edition a most complete and efficient course, and one especially adapted for boys commencing the subject.

Picture Lessons in Natural History. A series of diagrams on roller. (London: G. W. Bacon and Co., 1897.)

THE four sheets before us, which, we presume, form only a portion of the series, include the Protozoa and "Invertebrates." From all points of view they seem admirably

adapted to give to the young student a clear idea of the leading structural features distinctive of the different groups of animals. The figures are well selected, well drawn, and well coloured, and are of a size sufficiently large to display the structure of each type of animal. The letter-press is written in exact and yet such popular language as to be easily understood by the most unscientific.

Although the author has seen fit to conceal his identity, certain peculiarities in spelling (*e.g.* "armored" and "centipeds") suggest that he is an American. It would have been better if a little more attention had been given to proof-reading, and we should not then have met with "chitin" on one sheet, and "chitine" on the next, while certain errors in punctuation would have been avoided. It seems a pity to allude to the argonaut as the nautilus, and a figure of the pearly nautilus ought certainly to have been introduced. We fancy, too, that the common gaper (*Mya*) will be somewhat unfamiliar to English students under its American title of "clam." R. L.

A Guide to the Fossil Invertebrates and Plants in the Department of Geology and Palæontology in the British Museum (Natural History). Pp. xvi + 158. (Printed by order of the Trustees, 1897.)

THE guide-books prepared by officials of the Natural History Museum at South Kensington, to interest visitors in the collections under their charge, are models of what guide-books should be; they are concise in text, often well illustrated, and marvellously cheap; and the persons who digest them obtain a liberal education on the subjects with which they deal. In this new Guide, prepared under the direction of Dr. Henry Woodward, the fossil invertebrates and plants represented by specimens and drawings in the Natural History Museum are described; the characteristics of the living organism, as well as of the parts found in a fossil state, being placed before the reader. With this Guide in his hand, the student of geology and palæontology will be able to derive the fullest advantage from the admirably-arranged geological record at South Kensington.

Report on the Causes and Prevention of Smoke from Manufacturing Chimneys. By Dr. Harvey Littlejohn, M.A., M.B., B.Sc., Medical Officer of Health. Pp. 51. (Sheffield: Wm. Townsend and Son, 1897.)

DR. LITTLEJOHN drew up this report, upon the subject of the smoke nuisance in Sheffield, at the request of the Health Committee. He gives a short account of the past history of the subject, which occupied the attention of a Select Committee of the House of Commons so far back as 1819. Sheffield has an unenviable notoriety for smoke, owing, of course, to the fact that a large number of its manufactures depend almost wholly upon the combustion of coal. Dr. Littlejohn suggests that further restrictions be imposed on the amount of smoke emitted by steam-boiler furnaces, but no special form of apparatus for preventing excessive smoke is recommended, the opinion being that greater care and attention in firing would considerably lessen the nuisance.

Birds of Our Islands. By F. A. Fulcher. Pp. 368. (London: Andrew Melrose.)

WITH the multitude of readable books which now exist on British birds, it is almost a reproach to be without a knowledge of bird-life. In this dainty volume the characteristics and habits of birds, and the curiosities of bird-land, are pleasingly described. The book is not an exhaustive treatise, but a collection of word-pictures drawn by the author in various parts of the British Isles. It is simple-worded; nevertheless, it is instructive, and it will lead its readers to look about them so as to see for themselves how interesting are the works of nature. The book would be a very acceptable present for a boy with a taste for natural history.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Theory of Dissociation into Ions.

I AM glad that Mr. Dampier Whetham has noticed the two experiments which I adduced against the present theories of osmotic action and dissociation respectively. The force of the first of these experiments he admits, but, as regards the second, I fear that he can hardly have realised the true results of the experiment, or else I do not realise the meaning of the explanation which he offers of it.

The experiment was: That when a mixture, represented by $100H_2O + H_2SO_4$, is put into excess of acetic acid, the lowering of the freezing-point of the latter shows that the mixture contains less than 101 acting units, instead of more, as would be the case if the H_2SO_4 molecule was dissociated into ions. The actual number of acting units indicated was about 70. (I have only an abstract of the paper by me: it will be found in the *Berichte*, 24, p. 1579.) Mr. Whetham's explanation is that the acetic acid takes the water away from the sulphuric acid, and this latter goes into solution as such in the acetic acid, and in this solvent it is undissociated. But even if this were so—and a determination of the conductivity of the complex solution should tell us at once whether it is, or not—we should still have our 101 acting units ($100H_2O$ and H_2SO_4) in the acetic acid, or, even if the sulphuric acid molecules combined with each other to form complexes, we should have, at any rate, something more than 100 units; whereas, as a matter of fact, we find only 70. Complete recombination of ions, and complete polymerisation of the sulphuric acid is quite incapable of explaining the reduction of the number of acting units present.

To quote some actual values: 16·8 molecules of water lower the freezing-point of 100 molecules of acetic acid 7·32°; 0·097 of a molecule of sulphuric acid lowers the freezing-point of 100 molecules of acetic acid 0·038°; the two together should lower the freezing-point of acetic acid 7·358° if they acted on it independently of each other, but the actual lowering which they produce is only 7·03°; therefore, they do *not* act independently of each other. The two together have even less action than the water only.

As an alternative explanation, Mr. Whetham suggests that "dissociation of the ions from *each other* does not forbid the assumption that the ions are linked with one or more solvent molecules." Quite true: but when a theory can only explain observed facts by driving us to assumption of the existence of such compounds as H_xH_2O and $SO_4\,yH_2O$, I venture to think that that theory must be somewhat shaky.

Harpenden, May 1. SPENCER PICKERING.

I AM very glad that Mr. Pickering has given further details of his experiment. From his former letter I did not gather that the number of acting units indicated by the freezing-point of the solution of $100H_2O + H_2SO_4$ in acetic acid was as low as now appears. The result is most interesting, and seems to me to furnish strong evidence for the modification of the dissociation theory for which I am contending, under the belief that, in spite of the last paragraph of Mr. Pickering's present letter, it furnishes the best explanation of *all* the facts. Had the number of acting units indicated been nearer 100—say 90, or more—it would have been possible to explain the experiment in the first way which I suggested, for the freezing-point of a solution of water in acetic acid shows that some of the solute molecules are polymers of H_2O (Raoult's value for the molecular depression is 33·0, as compared with 38·8 found from Van 't Hoff's formula, which agrees well with Raoult's values for other substances). This would reduce the number of acting units in the case of the mixed solution also, and even complete dissociation of the sulphuric acid would be insufficient to bring that number up again to 100.

This explanation, however, seems to me to be entirely upset by the result that the lowering of freezing-point produced by a mixture of water and sulphuric acid is actually less than that produced by the water alone. Certainly, as Mr. Pickering says, the water and sulphuric acid "do not act independently of each other"—at least, when dissolved in acetic acid. I do not think it quite logically follows that they are combined when

alone; but it certainly seems probable, and I have no wish to raise such an objection.

If we admit, then, that combination does occur when sulphuric acid is dissolved in water, as there is much evidence to show, need we abandon the dissociation theory? I think not; in fact, Mr. Pickering admits that my alternative explanation meets the case under discussion.

Mr. Pickering has made no attempt to explain the electrical phenomena I described in your issue of April 29, by any means other than the assumption of dissociation of the ions from each other. I know the idea of such dissociation is abhorrent to people who are fortunate enough to possess an orthodox chemical conscience; but, till some one has accounted for the electrical relations in another way, its acceptance seems to me to be a necessary consequence of the facts.

I cannot quite see the force of Mr. Pickering's objection to the idea that the ions are linked with one or more solvent molecules. There is no need to assume the existence of definite compounds, which could be crystallised out and handled. If we admit the presence of charged ions free from each other, electrical forces will certainly exist between them and the solvent. We know too little, as yet, about the mutual relations of atoms and their charges, to picture exactly what occurs; but these forces must produce some sort of connection between the ions and the molecules of solvent. This connection, of course, only remains unmodified as long as the dissolved body keeps in solution.

Such a view of the dissociation theory seems to me to offer many advantages. It may be contrary to some *opinions*, but I do not think any *facts* have yet been pointed out which refute it. Till they are, it may possibly be of some use as a working hypothesis in the investigation of that complicated structure which we call a solution. W. C. DAMPIER WHETHAM.

Trinity College, Cambridge, May 5.

On the Feathers of "Hesperornis."

A NUMBER of years ago I published in NATURE (December 25, 1890, p. 176) my opinion "On the Affinities of *Hesperornis*," agreeing, at the time, with Prof. D'Arcy Thompson and others, that those toothed birds of the Kansas Cretaceous beds saw their nearest allies in existing birds in the Loons and Grebes, or in the typical Colymbidine assemblage. In other words, the now-living pygopodous birds, such as *Urinator*, *Colymbus*, and so forth, are, by descent, the modern representatives of the ancient *Hesperornithidæ*, whether that descent or origin be direct or indirect. There are osteological characters, which the limitations of space will forbid dwelling upon here, that tend to convince me of the probability of the Grebes (*Podicipoidea*) being an earlier offshoot of the pygopodine stem than the *Urinatoroidea*, and so more nearly related to *Hesperornis* than the latter birds.

Re-stimulated by a brief article, by Prof. S. W. Williston, in *The Kansas University Quarterly* (vol. v., July 1896, pp. 53, 54, plate ii.), entitled "One of the Dermal Coverings of *Hesperornis*," Prof. O. C. Marsh takes occasion, in a recent issue of NATURE (No. 1432, vol. lv., April 8, 1897, p. 534), to once more advance the theory—and one which originated with him, and, fortunately, has received but meagre support—of *Hesperornis* having been nothing more nor less than some peculiar kind of "a swimming ostrich." This view of its taxonomic position has never been accepted by the present writer; and it would seem that many other comparative anatomists experience quite as much difficulty in believing that those ancient divers were any more "swimming ostriches" than the modern types of the *Struthionidæ* are a sort of group of gigantic terrestrio-cursorial divers.

Prof. Marsh is not the only writer that has been led astray in some parts of avian classification by employing what have been called "struthious characters" in avian osteology, and now he thinks his views are supported by the recent discovery of Williston, referred to above. Having carefully examined the published plate of the latter author, I must say that I am quite sceptical as to what he believes to be long tarsal feathers in *Hesperornis*. Surely, in the figure, the resemblance to feathers is very remote; and, quite as surely, long, drooping plumaceous feathers hanging down *to the feet* in a big, powerful *diver*, would in no way whatever assist it in either swimming or diving. In fact, just so soon as these soft, plumaceous feathers became thoroughly wet, they would naturally form a serious impediment to the proper use of the pelvic limbs in their forward and backward strokes; and one has but to study the action of these limbs in swimming, in our modern Loons, to appreciate this point. That *Hesperornis* possessed some kind of a plumaceous plumage, however, I long ago believed, and see no reason to change that opinion now.[1]

Plumaceous plumage was very likely far more prevalent among the earliest birds in time, than it is now among the modern types; and this applies absolutely to not a few characters in the skeleton. The latter, along whatever line we may trace them, are evidences of an approach reptile-wards, and by no means always point to struthionine affinity. Certain peculiarities in the pelvis, and at the base of the cranium, when associated with certain others, have, as I say, been unfortunately termed "struthious characters," and, with this mistaken idea operative, our more superficial avian anatomists can see but little beyond "ostrich" in either *Finamon* or *Apteryx*. Not so, however, is this the case with the more profound researchers, of which Prof. Max Fürbringer is so able a representative. There is no more ostrich in *Hesperornis* than there is diver in *Struthio*—how much of the latter there may be, I willingly leave Prof. Marsh to consider. R. W. SHUFELDT.

April 28.

On Augury from Combat of Shell-fish.

IN his "Jôzankidan Shûi" (published about 1767, tome i. fol. 3, *a*) Yuasa Shimbei, a Japanese literatus (1708–81), writes on this subject thus:—"Noma Samanoshin narrated that the destiny of a belligerent could well be foretold by means of the 'Tanishi.'[2] If two groups consisting each of three of this shell-fish be placed in opposite corners of a tray, the three animals representing the future conquerors would advance, while the others, which are doomed to defeat, would withdraw. This method was approved by repeated experiments during the siege of Osaka [1615].[3] Every time the experiment was carried on, it never failed for the three 'Tanishi,' respectively designated Hideyori, the lord of the castle, and his two generals, Ôno and Kimura, to be driven in corners by other three which were representing the leaders of the besieging army, Prince Iyeyasu, Ii, and Todô. Thence it is confirmed that there is no better method of foretelling the decision of a war [here Noma's narrative ends]. The same method is given in detail in 'Wu-pei-chi' [by Mau Yuen-i, completed 1621], which is to be consulted for its particulars." Unfortunately all four copies in the British Museum of the Chinese work, here referred to, are wanting vol. clxxxvi., wherein further details of the method are said to be found.

Besides, two older Chinese works, both of which I have never seen, viz. Fung Ching's "Pan-yu-ki"[4] (written *circa* 990–94) and Luh Wei's "Kwei-che-chi"[5] (twelfth century) are said to describe this method of augury to have been of old used in the region of Ling-Nan (which comprised the present provinces of Kwang-Tung and Kwang-Si).

In connection with Yuasa's statement above quoted, the following notice, by Etienne Aymonier, of a Cambodian mode of divination is equally interesting:—"Si une armée étrangère fait invasion dans le royaume, beaucoup d'habitants prennent deux *Khchau*,[6] placent au fond d'un bassin, d'un récipient, un peu de sable pour faire une petite arêne et assez d'eau pour recouvrir les deux coquilles. Ils allument des bougies et des baguettes odoriférantes, invoquent les divinités protectrices du royaume, les prient d'indiquer l'issue de la guerre au moyen de cette petite naumachie. Les *Khchau* représentant les belligérants luttent jusqu'à ce que l'un des deux soit culbuté"[7] ("Notes sur les Cou-

[1] See my article, "Feathered Forms of Other Days," *The Century Magazine*, January 1386, p. 357.

[2] "*Tannigi* are the common black Land Snails gather'd for Food in muddy Rice Fields. . . ." (Kaempfer, "History of Japan," 1727, vol. i. p. 141). It belongs to the genus Viviparus, and is *V. japonica*, if I remember correctly.

[3] For this event see, *e.g.*, Caron's "Account of Japan," in Pinkerton, "Voyages and Travels," 1811, vol. vii. p. 616; "Diary of Richard Cocks," 1883, *passim*.

[4] Referred to in Li-Ye, "King-chai-ku-kin-tau" (written *c.* 1234, Brit. Mus. copy, 15,316, *d*, tome iv. fol. 27, *a*).

[5] Quoted in the Grand Imperial Cyclopædia, "Ku-kin-tu-shu-tseih-ching," sec. xix. tome clxiii. sub. "Lo-pu-ki-shi," fol. 3, *a*.

[6] J. Moura, in his "Vocabulaire Français-Cambodgien, &c.," Paris, 1878, simply explains the word "khchau" as "coquille." From parallel instances it is highly probable that this is, too, a species of the Paludinidæ.

[7] This notice reminds me of an old Japanese tradition, which is this. "When the battle of Dannoura was about to be fought (1185) [for which battle see Adams, "History of Japan," 1874, vol. i. p. 36], Kumano-no-Bettô Tansô, a warlike priest, who was wavering in question which of the

tumes et Croyances superstitieuses des Cambodgiens," in *Cochinchine Française: Excursions et Reconnaissances*, No. 16, p. 142, Saigon, 1883).

So far the practice of augury from combat of shell-fish appears to be a peculiarity of the peoples in the Far East. Is there any instance of the same method described in other parts of the world?[1] KUMAGUSU MINAKATA.

May 3.

Luminous Phenomena Observed on Mountains.

On Easter Monday, 19th ult., I was ascending Braeriach by its well-known northern ridge, and, shortly after I had crossed the "snow-line," I witnessed a phenomenon of great beauty, the explanation of which I cannot give. The edge of my plaid, of my gloved hands, of my knickerbockers, &c., was bordered by a two-inch band of brilliant violet light, at the moment of beginning any movement. The light was not visible around anything at rest, nor did it persist; but only showed at the moment when rest was changed for movement.

My attention was directed to this for a very short time only, for heavy snow began to drive in my face, and I had to watch where I was going, as the immediate surroundings included dangerous ground.

After my return, I found an account of a somewhat similar appearance in the *Cairngorm Club Journal*, vol. i. p. 159. I copy the account as there given by Dr. John Gordon, of Aberdeen:—

"Half-way across the snow-slope, while the sun was somewhat obscured, but was still sending a considerable intensity of light, we observed a strange phenomenon. On the side of our body next the snow-slope there was a nimbus of violet light, which clung to clothes, naked fingers, and the shaft of the ice-axe. So plentiful did it appear in the palm of the hand that it looked at times like a pool of violet ink, and one thought it could be pitched away. On shaking the hand, however, the nimbus clung, and was not to be removed. Occasionally the colour varied, taking on shades of brownish-yellow and blue, but violet was the most marked colour. At another time, in much the same condition of light and snow surroundings, one of the party, who was very proud of the beauty of the silver case of his compass, was disgusted to find that it had a distinctly yellow, pinchbeck look. This light refraction or polarisation [?] was not so evident to some of the party, but the writer has observed it before in similar circumstances and atmospheric conditions."

I may add that, in my own case, no direct sunlight reached me, as I was in the lower part of a dense cloud or mist. Some of your readers may offer an explanation of this remarkable and beautiful appearance. C. G. CASH.

Edinburgh Academy, May 3.

The Utility of Specific Characters.

UNDER the above heading, in your issue of April 1, Mr. J. T. Gulick has an interesting communication, in which he asks whether it is possible to explain right-handedness, the dextral or sinistral coil of snail-shells, and similar features, as having any utility to the species of which they are certainly characteristic. Can it be due to natural selection that one snail is dextral, while another is sinistral?

It is a curious fact, I think first pointed out by Mr. Call, that in the American freshwater shells of the genus *Campeloma*, *sinistral shells are more numerous among the young than among the adults*. Thus, for example, Mr. H. A. Pilsbry (*Nautilus*, February 1897, p. 118), states that Miss Jennie E. Letson examined a lot of *Campeloma decisum* for him, with the result that, "out of 681 specimens, mainly adult, but including those from one-fourth grown up, none were sinistral. Out of 410 shells of the uterine young, 3 were sinistral, slightly over 0·73 per cent." He adds: "Probably all who have collected Campelomas have noticed the greater proportion of sinistral examples among the young shells. This doubtless indicates that the reversed condition is an unfavourable one for maturation."

So here, at any rate, we have some direct evidence as to selection. I think it will strike any one, that while left-handedness might be as good for the race as right-handedness, *there is a distinct advantage in uniformity*, and that consideration alone may perhaps suffice to explain Mr. Gulick's difficulty. Among plants it may seem less obvious, but where seedlings are crowded, uniformity may save space, just as a number of objects of the same shape can usually be packed into less space than those of diverse shapes. More plants can grow in a window-box where all bend to the light, than would be possible if half of them bent one way and half another.

There also occurs to me a theoretical consideration, perhaps of doubtful value. When a germ has diverse potentialities, so that it is left to germinal or environmental selection to decide which course it shall take in development, there must, apparently, be a certain waste of germinal energy. Any disadvantage thus arising is ordinarily much more than counterbalanced by the gain due to the adaptability of the organism, or in social species to the power of specialisation of the individual for social purposes. But it may be that when no such advantage is found, there exists a small disadvantage in deviations, potential or actual, from a common standard.

What we really need, in discussing these matters, is the observation of actual facts. The facts above related as to *Campeloma* are worth more than any amount of theoretical considerations. T. D. A. COCKERELL.

Mesilla, New Mexico, U.S.A., April 21.

The Motion of an Iron or Steel Ball in a Magnetic Field.

IN NATURE, April 29, a method, reprinted from the *Physical Review*, is given for illustrating the motion of a particle under the action of a force varying inversely as the square of the distance. I think it ought to be pointed out that the force on a small iron or steel ball, due to a single magnetic pole, is not inversely as the square of the distance. It may be shown without difficulty that if the strength of the pole be μ, the susceptibility of the iron or steel to magnetisation κ, and v the volume of the ball supposed exceedingly small, then the force towards the pole is

$$-\tfrac{1}{2}\cdot v\cdot\frac{\kappa}{1+\frac{4}{3}\pi\kappa}\cdot\frac{d}{dr}\left(\frac{\mu^2}{r^4}\right)$$

$$=\frac{2\kappa v}{1+\frac{4}{3}\pi\kappa}\cdot\frac{\mu^2}{r^5}.$$

Thus, assuming that κ is constant during the motion of the ball, which, of course, it is not, the force is inversely as the fifth power of the distance, and the curves given can not be regarded as even approximate representations of planetary orbits, but rather as rough representations of orbits described about a centre of force whose law is the inverse fifth (see "Tait and Steele," p. 151). ALEX. ANDERSON.

Queen's College, Galway, May 3.

THE NEW SOUTH AFRICAN MUSEUM.

THE new South African Museum is situated at the upper end of the Municipal Gardens, about a quarter of a mile distant from the old building, which will now be entirely occupied by the public library.

The new building consists of two floors, of which the upper one contains the principal exhibition rooms; the large room, measuring 63 feet by 41½ feet, is devoted to the birds, reptiles, and fishes of South Africa; and there also is the cast of the skeleton of the restored triassic reptile, *Pariasaurus bainii*, Seeley. It is also hoped that at some future time other casts and originals of some of these remarkable extinct forms may be exhibited, among which we may perhaps find the progenitors of our modern mammals. The corresponding room is devoted to the general collection of vertebrates. A small room contains the anthropological collection, both South African and general.

two antagonist clans to support—Minamoto or Taira—doubting the accuracy of an oracle given by his patron-god to induce him to serve under the White Banner [*i.e.* the Minamoto clan], caused seven white cocks to combat with seven red ones before the shrine of the same deity. And the result was that the red ones [which represented the Red Banner of the Taira clan] were all defeated by white ones, which impelled him to make up his mind to serve the Minamoto clan" ("Heike Monogatari," tome xi.).

[1] Of allied modes of divination about the decision of a war, I may instance the New Zealander's practice with sticks, and a Gothic king's experiment with swine (see Lubbock, "Origin of Civilisation," 5th ed., p. 245; and Mary Howitt's Appendix to Ennemoser's "History of Magic," ed. Bohn, vol. ii. p. 458).

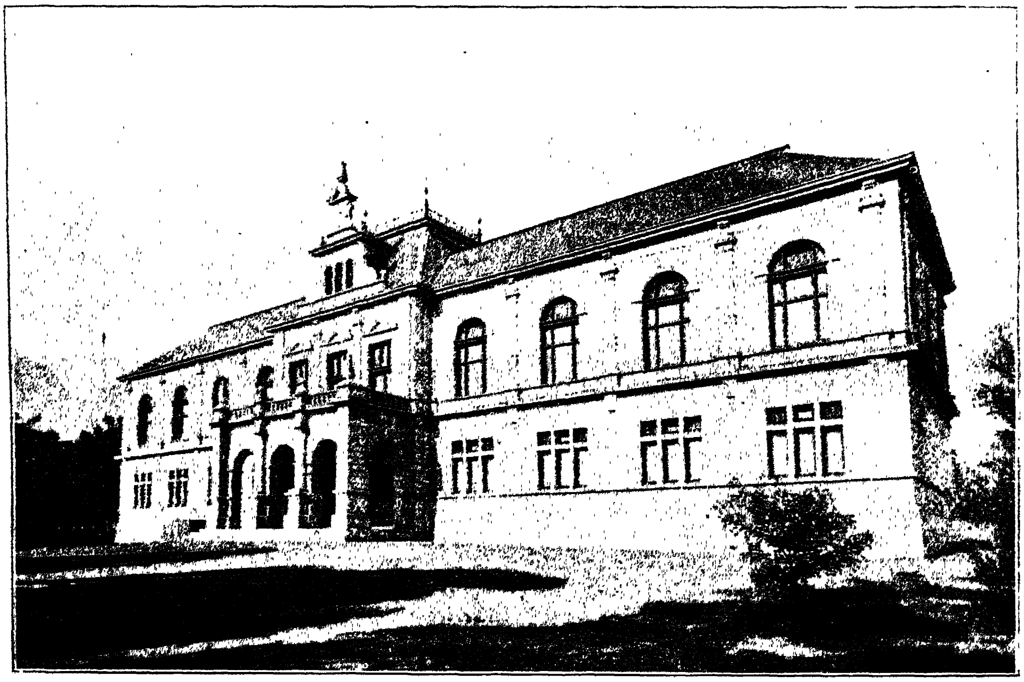
The remaining room is entirely devoted to the South African mammals, among which are an excellent series of antelopes, chiefly obtained for the Museum by Mr. Selous; and the white rhinoceros, which was shot in Mashonaland about two years ago by Mr. Eyre, and was presented to the Museum by the Right Hon. C. T. Rhodes.

The three rooms first mentioned are lighted by windows, and the cases placed at right angles, much in the same fashion as in the larger galleries of the Natural History Museum at South Kensington. The South African mammal room is lighted from above, and the cases extend all round the walls, together with four very large free standing cases arranged in the middle of the room. All the cases are made entirely of iron and plate-glass, on what is generally known as the Dresden system. This was found necessary in consequence of the great difficulty which has hitherto been met with owing to the warping of all woodwork in South Africa, which entirely prevents rooms are fitted with desk-cases, with underlying drawers, also entirely constructed of iron and glass.

The small rooms, together with those underneath the South African mammal room, are the offices, the library, and study-collections in cabinets and preserved in spirit. Apart from the main building is a large taxidermist shop and store room.

Great interest was shown in the recent formal opening of the Museum by the Prime Minister, Sir J. Gordon Sprigg. A long report of the ceremony appeared in the *Cape Times*, and is here abridged.

The Hon. J. X. Merriman, addressing Sir Gordon Sprigg, and those present, said it had fallen to his lot as the senior trustee to ask him to open the Museum. The occasion marked a very important stage in the history of the Museum, and he could wish it had fallen to some one more scientific than himself to sound the praises of the institution. But, in another way, it was fit that he should say a few words, as he was perhaps the only one in the assembly, except Sir Richard Southey, who



The New Museum at Capetown.

wooden cases from being secure from the attacks of insect pests.

On the ground floor, on either side of the entrance hall are two rooms; of these, the larger one on the left contains the invertebrate collections; the smaller, the antiquities. Amongst these latter, there are a certain number of pieces of glass and china of considerable artistic merit, brought to the Cape by the Dutch settlers in the early days; and also one of the so-called post-office stones on which, before any settlement existed, the captains of passing ships used to engrave the dates of their arrival and departure, and notices requesting subsequently-arriving captains to search near by for letters. Similar stones are still occasionally found in the centre of Cape Town, when excavations are made.

The corresponding rooms on the right of the entrance contain the geological collections; the general collection in the larger room, the South African in the smaller. In the latter a special feature will be the exhibition of specimens relating to the gold and diamond industry. These

recollected the Museum in its infancy. When a boy, in the year 1855, he was always interested in going to the Museum. It was due to two gentlemen who had now passed away, Mr. E. L. Layard and Mr. Charles Fairbridge, that the Museum was first founded. It was then put in the old Slave Lodge; and it was mainly owing to their exertions, and to the interest taken in it by Sir George Grey, that the new Museum and Library was built, and that the Museum migrated there, where it remained for a great many years. At first Mr. Layard was the curator; and amongst the trustees who deserved mention were Sir Richard Southey, who only vacated his office on being appointed Governor of Griqualand West, and Sir Thomas Maclear, the Astronomer Royal, who was now dead. The room was found to be totally inadequate to the size of the collection, and after some negotiations with the Government a grant was obtained, and the result they saw in the building they were now going to open to-day.

He thought it would be fitting that he should say a few words as to some of the aims and objects in arranging the Museum in that building. The prevailing idea, he was afraid, was that a museum was a collection of all sorts, and oddments and curiosities; and the name, like the honourable name of professor, had been a good deal brought down; for instance, they had Barnum's

Museum—and he was afraid people were inclined to imagine the Museum to cope with that magnificent receptacle for the bearded woman and the two-headed calf. The aim, however, of this Museum was that it should really be, in a sort of way, the home of research in South Africa; that whatever scientific research there was in South Africa should find its home within the walls of the South African Museum, and that the collections should be so arranged as to illustrate the different branches of scientific research in that country. The Museum was under the general direction of Mr. Sclater, who had thrown himself into his work with a zeal and efficiency which left nothing to be desired. He had taken upon himself the management of the special branch—that of mammalia—the largest animals of South Africa. These were a vanishing class, owing to the rapidity of progress; for the spirit of civilisation was rapidly destroying all these interesting animals, which made South Africa at one time famous throughout the world.

It was sixty years ago since the great naturalist, Darwin, drew a remarkable picture of the mammalia of South Africa. He drew attention to the fact that the mammalia of South Africa were the largest and most numerous in the whole world; and he compared them with the mammalia of Brazil, and showed in what an extraordinary proportion the weight of our animals exceeded that of the South American animals. Now they had got rid of their mammalia here, and were importing frozen meat; and this could hardly be said to be improving nature. Before the mammalia were extinct, it was very desirable that a collection of them should be formed, and they would see a beginning had been made in this direction. Another branch the assistant curator, Mr. Peringuey, had taken under his charge, viz. the important division of entomology, or the study of insects. Some people, little thinking of the important part insects played in the world, smiled, but it was an insect that cost France more than the Franco-Prussian war; it was an insect that formed their most acute political differences in this country. When he ran through the important part that insect-life played, he sometimes wondered how it was possible for man to exist on the face of the earth at the same time. They also had another gentleman working in the same direction as Mr. Peringuey, viz. Mr. Lounsbury, the able entomologist. They wished, however, to make the Museum the home of insect life—though not of live insects.

Dr. Corstorphine was in charge of the geological section of the Museum, which up to the present time had been neglected. Dr. Corstorphine was making good progress, and in connection with that the Geological Commission had its home in the South African Museum. Dr. Purcell, a South African, had set a fine example. After studying in the science schools of Europe, he came out here to spend his life; he was in charge of the invertebrate section; and finally there was Mr. Gilchrist, who had come out as an expert upon fisheries, and who was in charge of the marine section. So that all the branches were fairly well organised, and the scheme, they would admit, was a good one if it could be carried out. For the organisation the greatest thanks were due to his two fellow trustees, whose zeal and energy deserved all praise. On the Board of Trustees he represented the Philistine element, so he could lay no claim to credit for the scheme of scientific research.

Only one thing seemed to be lacking, and that was a very common thing indeed—that was, that they needed funds; they were crippled for want of money. Some of the gentlemen he had mentioned were working simply for the love of science, whilst others were working on a pittance which some of them would not think well to give to their upper clerks. They lamented in this country that they had not some of those liberal men who in America had identified themselves with scientific institutions. Parliament had been liberal enough in these matters, and it afforded him great pleasure in this connection to say that to Sir Gordon Sprigg they had a right to be thankful, because he had always acted to them, he would not say with liberality, because that was not the word to use in connection with public funds, but with a just appreciation which had not always been met with amongst his predecessors. Not only as head of the Government, but as a personality he called upon the Premier to formally open the institution in which they now found themselves.

Sir Gordon Sprigg said he remembered the South African Museum in the year 1858, in which year he first went to that country. From that time to the present, from a public, not from a scientific point of view, he had taken a very great interest in the institution, and it afforded him very great pleasure indeed to declare the Museum open to the public. Those who had had an opportunity of visiting the Natural History Museum at South Kensington would see that the trustees had endeavoured to follow out in every possible way the design of that great institution. After the very interesting speech delivered by Mr. Merriman, which explained the objects of the institution and the designs of the trustees who had brought it to its present condition—something like approaching to perfection—he would not weary them with any further words, but would simply declare the Museum open for the public. At the same time the trustees recognised the fact that they had never appealed to him in vain for funds, and so long as he held his present position they never would appeal to him in vain. From time to time, so long as he held the position he now held, it would always afford him great pleasure to submit to Parliament any proposals submitted to him for consideration.

Dr. Gill said he had been requested by his fellow-trustees to say a word about one who was one of his dearest friends, who worked hard under great difficulties before a liberal—or should he say a wise—Sir Gordon Sprigg arose. He was the one who really bore the burden and the heat of the day, one who under great discouragement persevered in creating the nucleus of the Museum they were now about to see—and that man was Roland Trimen, F.R.S. On an occasion like the present it would be a great mistake if they were to omit the name of one who had done so much for natural history in South Africa. Mr. Trimen laid the foundation of that museum; they all owed him a great debt of gratitude, and they ought to remember it on that day.

THE SCIENCE OF ART.

PERHAPS the learned Dr. Bastian, of Berlin, has appreciated more than any one else that the psychological aspect of anthropology requires far more attention than has yet been devoted to it; the present writer would venture to assert that it is the department of anthropology that most urgently requires students. No doubt the subject is difficult, but the reward will be great. Experimental and observational psychology have received but scant attention in this country, and the psychology of the lower races has been totally ignored by us.

Of late years several anthropologists have studied the origin and modifications of the decorative designs of savage peoples; but only a very few of these have recognised that the tracing out of the history of a pattern or a design is of minor importance compared with the psychological processes that induced the original selection of the motive, and that operated in its subsequent elaboration or simplification. The scientific study of decorative art is a branch of psychology.

The editor of our contemporary *Mind* also appreciates this fact, and so Prof. G. F. Stout has printed a paper on "Evolution and Psychology in Art," by Dr. Colley March, in the October number of that journal. Dr. March accepts the definition of art as given in Dr. Murray's great dictionary: "Art is the application of *skill* to implements of utility, to subjects of taste, such as poetry and dancing, and to works of imitation and design, such as painting, sculpture and architecture." For the sake of convenience, Dr. March divides art into: (1) Artifice, of purely utilitarian intention. (2) Artistic treatment, or the shaping or arrangement of the details, parts, colours or outlines of implements or structures, whether utilitarian or not, so as to "please the eye." (3) Ornament: works of utility are necessary; man is compelled to make things. We understand why, in the making, they should be artistically treated, for the eye has always been accustomed to see outlines that represent the most functionally useful, and utility is always pleasing. It is not quite so obvious why they should become the subject of Ornament. Ornament is a decoration applied to an object which could exist quite well without it. Several examples of every-day objects are given, which show that Ornament sprang from structural handicraft, and became

rooted in the mind by association of contiguity, and that thus an expectancy was raised for them of such urgency that transfer took place as occasion offered. The discussion of this subject takes up the greater part of the paper. (4) Embellishment is finery, which may be sexual, bellicose, proud, aggressive, or wanton, and not unfrequently these articles of embellishment cannot be regarded as examples of Fine Art. (5) The works of Fine Art can be sharply differentiated from Ornament. They have an altogether independent existence, and are not subordinate to serial repetition. It is their aim and end to excite a high order of emotion. If we admit that Fine Art exists solely for the purpose of furthering emotion, we may safely conclude that emotional craving originated it.

"In conclusion," writes Dr. Colley March, "the five elements of Art may be analysed upon an urn. Artifice has moulded a hollow vessel of earth, and has baked it so that it will hold water. As the gourd was in many cases its model, Expectancy has required its base to be much narrower than strict utility might have provided; but the ring that was once a stand for it has now become its foot. Artistic treatment has given it outlines that we, or others, call graceful; has coloured its clay, and washed its surface with a translucent glaze; and has carried aloft in symmetrical curves those handles that were once of ozier or of cords.

"Round the foot and shoulder and neck, Expectancy has drawn bands of Ornament, skeuomorphs [designs derived from technical methods of construction in handicraft] of binding, of basketry, or of textiles; and a phyllomorph [or plant-design] is parasitic upon them. Embellishment has hung a foolish chain in a festoon between the handles. And Fine Art has filled the middle zone with a bas-relief, or a painting, that moves the soul.

> 'What leaf-fringed legend haunts about thy shape
> Of deities or mortals, or of both,
> In Tempe or the dales of Arcady?'

Thus, revealed upon a vase, we witness not alone the elements of Art, but its history, its psychology, and its evolution." A. C. H.

ADAM HILGER.

By the death of Adam Hilger, which took place on April 23, the physical sciences, and especially astronomical physics, have suffered a loss which cannot be immediately made good. Standing in the front rank of practical opticians, he did much to promote scientific progress along various lines, his thorough scientific training enabling him to undertake optical work of the highest character.

Born in Darmstadt, in 1839, he early showed a marked inclination for the mechanical work in which his father was then engaged. For some years he was a mechanical engineer in Darmstadt, and he afterwards entered Ertel's famous establishment at Munich. He next came to London, but, though commanding a good salary, he found no opportunity of advancing his knowledge, and soon left for Paris, where he had the good fortune to find employment with the firm of Lerebours and Secretan. During this engagement he constructed many instruments, under the direct supervision of Foucault, and became fully acquainted with the theory, as well as with the practice, of his art. After the war of 1870 he came to London with his family. Here he was engaged with Mr. Browning, at first as a simple workman, but afterwards as foreman. Having completed a five years' contract, he commenced business on his own account at Islington. At these well-equipped works he produced the instruments which have brought him such a high reputation among physicists and astronomers throughout the world. He was especially skilled in manipulating quartz and Iceland spar for work on the ultra-violet rays, and had lately succeeded in making very perfect achromatic combinations of these materials. The special qualities of the new Jena glasses were also well known to him, and by their use he produced achromatic lenses of very short focal length, as well as prisms of very high dispersion.

We understand that the business will be, in all probability, continued by Mr. Otto Hilger. A. F.

A NIGHT IN MID-MAY.

NOW tender eve has kissed the drooping eyes
Of sleeping daisies; incense floods the air,
Bowed Nature kneeling at her vesper prayer;
Mid rustling leaves the pensive night breeze sighs.
In heaven's great garden brighter flowers arise;
While throned Arcturus fires the southern skies;
Aglow the coils of Berenice's Hair;
Her wonted path the patient moon makes fair.
Calm whisperers! of splendours far away,
Glad messages in golden light ye bring—
A heart's desire fulfilled one happy day,
In perfect love and never ending spring,
Where painless pleasure shall no more take wing,
Nor spectral winter close the eyes of May.

M. C. L.

NOTES.

THE Bakerian Lecture will be delivered at the Royal Society on Thursday next, May 20, by Prof. Osborne Reynolds, F.R.S., and W. H. Moorby. The subject will be the mechanical equivalent of heat.

DR. E. J. STONE, F.R.S., Radcliffe Observer at Oxford, died on Sunday last. Astronomy has thus lost one of its foremost workers.

WE join in the general expression of regret at the death of the Duc d'Aumale, a very distinguished member of the French Academy. He spent a great part of his life in England, and received the honorary D.C.L. at Oxford in 1891. He frequently appeared at the Athenæum Club, and his interesting personality was therefore known to many who were not his fellow-countrymen. By a deed of gift, executed in 1884, the Duc d'Aumale's château at Chantilly, and all its precious contents, was presented to the Institute of France, in trust for the French nation, subject only to his life interest in the château. The Paris correspondent of the *Times* gives particulars of this splendid gift. By the terms of the bequest Chantilly must preserve the character of a museum. The exterior wings are assigned as lodgings for the three curators, and the museum, under the supervision of the Institute, will be an institution open to the public. Besides this, the Institute, to meet the expense of the preservation of Chantilly, is given the forest, the annual clearings in which produce about 100,000 francs. It also possesses other portions of the estate, which will produce more than the sum necessary for the maintenance of a museum. France will thus always possess a magnificent monument to the memory of one who held national welfare very dear.

THE annual conversazione of the Society of Arts will be held at the South Kensington Museum, on Wednesday, June 16.

THE Yachting and Fisheries Exhibition at the Imperial Institute will be opened by their Royal Highnesses the Prince and Princess of Wales, on Monday, May 17.

THE *Lancet* states that the Government of India, recognising the arduous and valuable nature of M. Haffkine's recent work in connection with the bubonic plague, has sanctioned the grant of a monthly salary of Rs. 2000 to him instead of the

allowances hitherto given. This arrangement is to have a retrospective effect from the date on which he began work in Bombay.

THE Committee of the Puffin Island Biological Station have decided to offer facilities to students and others for the pursuit of scientific research at the station during the summer months. The island is well situated for the study both of marine zoology and ornithology, and the station is provided with sleeping accommodation in addition to the usual laboratories. Those wishing to avail themselves of the present opportunity should communicate with the Director, Prof. P. J. White, University College of North Wales, Bangor.

AT the annual meeting of the Institution of Civil Engineers, recently held, the Chairman was able to announce some important changes which have recently been made in the management of this Society, which are calculated to bring its proceedings more up to date. Hitherto, new members and associates have been admitted on a kind of guarantee, signed by a certain number of existing members, that the applicant is, by training and experience, duly qualified to act as a Civil Engineer; and although in recent years the Council have taken steps to ascertain that the candidate has been properly educated, no direct examination has been required. In future, in addition to the requirements now in force, a test examination of the general and scientific knowledge of candidates for election into the class of associate members will be required. A further departure from old customs, which has also recently taken place, is that members can now vote for the annual election of the President and Council by balloting papers, without personal attendance at the meetings, as used formerly to be necessary. The roll of members of this Institution now numbers 6204, and is constantly on the increase. The last year's annual income amounted to 22,285*l*. A large amount out of the capital funds belonging to the Society has recently been expended on the new building in Great George Street.

WE regret to announce the death, on the 7th inst., of Mr. Abraham Dee Bartlett, the well-known resident Superintendent of the Zoological Society's Gardens in the Regent's Park. Mr. Bartlett was born in London in 1812, and was formerly in business as a dealer in natural history specimens. After a short period of office as head of the Natural History Department at the Crystal Palace when it was instituted, Mr. Bartlett was appointed Superintendent of the Zoological Gardens in 1859, shortly after Mr. Sclater became Secretary, and continued in the efficient performance of his duties until about six weeks before his decease. In his practical knowledge of living animals Mr. Bartlett was unrivalled, especially as regards mammals and birds. No one knew better than he whether an animal offered for sale was sound or sick, or was a better judge of its value. He was also an excellent observer of the habits and structure of the animals under his charge, and communicated many valuable papers to the Zoological Society's scientific meetings on these subjects. One of the most remarkable of these was that on the shedding of the horns by the Prongbuck (*Antilocapra americana*), published in 1865. Mr. Bartlett's discovery of this curious phenomenon was at first discredited by the American naturalists, but the fact is now universally admitted.

THE death is announced of Mr. Matthew Carey Lea, of Philadelphia, at the age of seventy-four. From an obituary notice in the *American Journal of Science* we derive the following particulars of his work:—"Mr. Carey Lea was elected a member of the National Academy of Sciences in 1892, and the list of his more important papers then published contained fifty-four titles. These investigations for the most part related to the chemistry of photography, and especially to the action of light and other forms of energy upon silver salts. He described photo-bromide and photo-iodide of silver, and in 1887 published a paper on the 'Identity of the photo-salts of silver with the material of the latent photographic image.' His most remarkable discovery, however, made in 1889, was that silver is capable of existing in three allotropic states. The first is allotropic silver proper, 'which is protean in its nature, may be soluble or insoluble in water, may be yellow, red, blue or green, or may have almost any colour, but in all its insoluble varieties always exhibits plasticity; that is, if brushed in a pasty state upon a smooth surface, its particles dry in optical contact and with brilliant metallic lustre. It is chemically active.' The second is intermediate in character, may be yellow or green, always shows metallic lustre, is never plastic, and is chemically indifferent. The third is ordinary silver."

WITH much regret we have to announce the death, on May 5, of Mr. J. Theodore Bent, who had just returned from a journey, with Mrs. Bent, in Sokotra, and in southern Arabia, in the course of which they had made some remarkable discoveries. Both had suffered from malarial fever, and Mr. Bent succumbed to a subsequent attack of pneumonia. For twenty years Mr. and Mrs. Bent spent a large part of each winter in travelling, and their later journeys have been described in several books. The more important were those in Greece and Asia Minor, in the course of which Mr. Bent acquired remarkable facility in modern Greek, and established his reputation as an archæologist; in the Bahrein Islands of the Persian Gulf; in Mashonaland, where he was the first to systematically study the wonderful ruins of Zimbabwe; in Abyssinia; on the Red Sea coast of Egypt; and to Hadramut, in southern Arabia. A leading object in the later journeys was to investigate the extension of the Sabeans at the period of their prosperity as a trading nation. Mr. Bent read many important papers to the Royal Geographical Society, the British Association, and other Societies. His unique collections of antiquities have been exhibited at the Royal Society's conversaziones, and his gatherings from numerous wanderings made his house a veritable museum. While his death is a serious loss to archæology and geography, the personal sorrow which it occasions is greater than in the case of most explorers. Mr. Bent had a very large circle of devoted friends, which, with a frank kindliness peculiarly his own, he was ever widening. The unaffected heartiness of his manner to all, and his readiness to assist every one engaged in kindred studies, will not soon be forgotten. Although he died at the age of forty-five, Mr. Bent leaves behind him the memory of more kind actions and helpful words than can be placed to the credit of most men whose lives have ripened into old age.

THE new Ostrich-and-crane-house in the Zoological Society's Gardens has lately been completed, and is already fully tenanted. The compartments on the south side accommodate all the struthious birds, which have now for the first time been brought together from different parts of the Gardens. The most recent addition is a fine adult male of the Somali ostrich (*Struthio molybdophanes*), remarkable for the bluish tinge of the naked parts, which in the Northern ostrich are red. The sixteen compartments on the north side are occupied by a fine series of cranes and storks.

THE anniversary meeting of the British Ornithologists' Union was held in the Zoological Society's Offices, 3 Hanover Square, on the 5th inst.; Mr. P. L. Sclater, F.R.S., in the chair. The report of the Committee gave a very favourable account of the Union's affairs, and of the progress of its journal, the *Ibis*, which has now been carried on successfully for thirty-eight years. Twenty-four new members were elected, raising the strength of the Union to more than 300. For the ensuing

year Mr. F. D. Godman, F.R.S., was elected president, and Mr. O. Salvin, F.R.S., secretary, the editors of the *Ibis* (Messrs. Sclater and Saunders) remaining as before.

THE first of a series of ten lectures, on the structure and distribution of birds, was given at the Zoological Society's Gardens on May 6, by Mr. F. E. Beddard, F.R.S., prosector to the Society. The lecture dealt with the main points in the external and internal anatomy of the class, special weight being laid upon those characters which are associated with the flight of birds. The lecturer gave a short *résumé* of the characters of the feathering of birds, not omitting to mention that, at present, baffling problem—the presence or absence of the fifth cubital remex. Attention was directed to the fact that although, on theoretical grounds, a continuous feathering, like that of the penguins and struthious birds, was to be looked upon as the primitive state of affairs, it was doubtful whether, in existing birds, the close feathering was not a secondarily acquired character. In support of this, the transitory existence of marked apteria and pterylæ in the chick-ostrich, as first described by Miss Lindsay, was pointed out. In describing the essential features of the skeleton, the lightness of the bones, the massing of the chief weight in the middle of the body, the structure of the hand, and various matters illustrative of the adaptation of that part of the organism to the purposes of flight, were dwelt upon.

PROF. HANKIN'S report to the Bombay Chamber of Commerce, concerning the infection of grain and the vitality of the bacillus of plague in infected grain, is thus summarised in the *British Medical Journal*. (1) The microbe has not been found in either stored grain or in parasitic insects inhabiting grain. (2) Grain can be infected by a pure culture of the bacillus of plague, so that an extract made therefrom will cause death from plague in animals (mice). (3) The potency of grain-infected extract rapidly diminishes, so that in a few days it does not kill. Thirteen days is the extreme limit of possible potency; but Prof. Hankin is led to the belief, by his experiments, that plague bacilli obtaining admission to grain stored as on board ship would certainly become non-infective in four to six days.

THE definition of a standard or standards of thermal efficiency for steam-engines was referred to a Committee of the Institution of Civil Engineers last year; and the gist of the conclusions, which have just been arrived at, is as follows: (1) That the statement of the economy of a steam-engine in terms of pounds of feed-water per horse-power per hour is undesirable. (2) That for all purposes, except those of a scientific nature, it is desirable to state the economy of a steam-engine in terms of the thermal units required per horse-power per hour (or per minute), and that if possible the thermal units required per brake horse-power should also be given. (3) That for scientific purposes the thermal units that would be required by a perfect steam-engine working under the same conditions as the actual engine should also be stated. The proposed method of statement is applicable to engines using superheated steam, as well as to those using saturated steam, and the objection to the use of pounds of feed-water, which contain more or less thermal units according to conditions, is obviated; while there is no more practical difficulty in obtaining the thermal units per horse-power per hour than there is in arriving at the pounds of feed-water. For scientific purposes the difference in the thermal units per horse-power required by the perfect steam-engine and by the actual engine shows the loss due to imperfections in the actual engine. It is pointed out that a further advantage of the proposal is that the ambiguous term "efficiency" is not required.

IN the *Mittheilungen der K. K. geographischen Gesellschaft*, in Vienna (vol. xl. Nos. 1 and 2), there is an exhaustive memoir on the Karlseisfeld or Hallstätter Glacier of the Dachstein. The first part is devoted to a minute examination of the topography of the region, and the second to an account of the methods and results of a careful survey made by the author. An excellent map is appended.

THE current number of *Petermann's Mittheilungen* contains the first instalment of a new estimation of the areas of non-European river-basins, by Dr. Alois Bludau. The numbers for South America are here given. Sixteen separate basins make up a drainage area of 16,275,000 square kilometres to the Atlantic; the Pacific slope, divided into four regions, accounts for 1,056,000 square kilometres; leaving the Titicaca and similar regions, without an outlet to the sea, the remaining 274,000 square kilometres.

WE have received from the author a contribution to the rapidly increasing literature of limnology—"Zur Entstehung der Alpenseen," by Dr. L. Swerinzew. Dr. Swerinzew criticises a good deal of recent work somewhat severely, and comes to the conclusion that a number of the types of lake-basins now regarded as different, are really identical as regards their mode of origin and development. About 90 per cent. of the Alpine lakes found in valleys are held to have been formed simply by the erosive action which gave rise to the valleys themselves.

M. DE LAPPARENT contributes to *La Nature* a note on some further considerations suggested by Nansen's discovery of a deep Arctic basin. He points out that the area we may now assign to the Arctic Ocean is almost the same as that given by Murray to the Antarctic Continent—about four and a half million square kilometres, while the depths observed by Nansen correspond in order of magnitude to the heights observed by Ross; and it is remarkable that a small area like the Arctic Ocean should give soundings equal to the averages obtained in the Atlantic and Pacific. These considerations, similar to those which have led Mr. Lowthian-Green to assume that the earth has a tetrahedral form, suggest that it may really be top-shaped, the spinning point, as it were, being the South Pole. Such a supposition would tend to reconcile the differences of astronomers and geodesists as to the ratio of the polar and equatorial diameters; for the latter base their value of the polar flattening, 1/294, upon measurements made almost entirely in the northern hemisphere. The value obtained by M. Tisserand from the precession of the equinoxes, 1/297, may be found sensibly correct, if the existence of the south polar protuberance, and consequent effects upon the form of the sea surface, are admitted.

SINCE the great earthquake of 1855, the strongest felt in Tokio was that of June 24, 1894, which forms the subject of a valuable paper contributed by Prof. F. Omori to the Italian Seismological Society. The entire land-area disturbed was about 110,000 square miles. The meizoseismal area was a band lying to the east of Tokio, and running north and south, from Iwatsuki to the Bay of Tokio. This band occupies the lowest part of the plain of Musashi, which is the continuation of the axis of the bay, and the earthquake was probably connected with a long fault lying beneath the meizoseismal band. Records of the earthquake were obtained at two observatories in Tokio. At one of these, situated on high and hard ground, the earthquake consisted of one prominent oscillation, preceded and followed by smaller vibrations; the maximum horizontal displacement being 73 mm. in the direction S. 70° W. and N. 70° E., and the maximum horizontal acceleration 444 mm. per sec. per sec. At the other observatory, which is on low and soft ground, the horizontal displacement was 130 mm., and the maximum acceleration about 900 mm. per sec. per sec. Prof. Omori believes that near the epicentre of a great earthquake, the movement is generally of the same simple character

as that above described, combined with a definite direction of the shock. Slighter earthquakes usually consist of a great number of small vibrations of nearly equal amplitude executed in different planes.

THE method of the computation of the Chinese calendar is described with clearness by Paul d'Enjoy in the *Bulletins de la Soc. d'Anthropologie*, 1896, p. 562. Every year is named by a combination of two words according to a fixed rule, and the special combination is supposed to indicate the fortunes of the year. The year 1896 was the period of the external hearth and the monkey; that is a time of dangers from abroad, which must be met by cunning and dexterity. Unfortunately for the Chinese, it was the Japanese that exhibited these qualities! In 1897 the Chinese enter calmer times, under the auspices of the internal hearth and the chicken. Next year the activity of the nation will be diverted from the cultivation of the soil, and turned towards watchfulness and the protection of the home, as the yearly combination is waste-land and dog. The months, weeks, days and hours are also described. Each of their hours corresponds to two European hours, of which seven belong to the day, and five to the night; the first hour commences at 11 o'clock at night. M. d'Enjoy states that Belgium is about to adopt the principle of the Chinese double hours for the official railway time-tables.

WHAT Sir William Flower has to say upon "Natural History as a Vocation," carries great weight; so parents with children who have proved the earnestness of their interest in nature's life and moods, should turn to an article in *Chambers's Journal* (May) if they wish to know exactly what are the prospects of the livelihood obtainable by following the inclination. "As to natural history as the regular occupation of one who has no other means of living," says Sir William Flower, "I have little to say that is favourable, as it is about the worst paid and least appreciated of all professions." There are signs, however, that the prospects are brightening, and the youth who feels confident of his ability "to scorn delights and live laborious days," may eventually find his way to a position as a lecturer, demonstrator, or curator. To pursue the vocation with any chance of success, he must have a considerable knowledge of modern languages and other subjects, as well as of natural history. He should begin wisely to collect specimens, and should educate himself by his collection; for, Sir William Flower points out, "The arrangement of a collection not only teaches the nature and properties of the objects contained in it; it also stimulates a desire to know more of the similar objects not contained in it, but to be found in other and larger collections. Still more important than this, as an educator, it calls out many valuable practical qualities: originality, order, neatness, perseverance, taste, power of discriminating small differences and resemblances, all of which will be found useful in other spheres of life." Sir William Flower's first "museum" was contained in a large, flat, shallow box with a lid; and one of the first specimens he possessed was a badly stuffed specimen of the dipper or water ousel.

IN the *American Journal of Mathematics*, xix. 3, Dr. G. H. Bryan gives a brief account of certain applications of the theory of probability to physical phenomena. The main difficulty in accounting for such phenomena by means of the principles of theoretical dynamics lies in the fact that the equations of motion of an ideal system always represent reversible processes, which in nature are conspicuous by their absence. The author proceeds to examine how far the difficulty may be overcome by introducing the theory of probability, especially in connection with the kinetic theory of gases, and he gives a short *résumé* of certain investigations by Prof. Boltzmann, from which it is found that, under certain assumptions, the most probable distribution of the coordinates and momenta of the molecules of a gas is that which has been termed the Boltzmann-Maxwell distribution. Unfortunately, however, the proofs involve certain initial assumptions, and, on varying the nature of these, the results as to the most probable final distribution will be different. It would thus appear that even probability considerations do not afford unassailable proofs of the law which forms the usually accepted basis of the kinetic theory—a result completely in accordance with Mr. Burbury's recent investigations, according to which assemblages of densely-crowded molecules do not conform to that law.

FROM a number of papers before us dealing with kathodic and Röntgen rays, we extract the following. Dr. Garbasso (*Nuovo Cimento*, 4, iii.), in discussing the effects of products of combustion on the length of the electric spark, considers that if flames produce certain actions on the sparks, like those of Röntgen rays, it is because they are the seat of chemical phenomena, since in the products of combustion there exist dissociated molecules, in other words electrified particles. It seems probable that Röntgen rays and ultra-violet light act on sparks for the same reason.—Dr. Quirino Majorana (*Atti dei Lincei*, vi. 5) discusses the electrostatic deviation of kathodic rays, such as can be studied by the introduction of a second kathode or anode in the discharge-tube.—M. L. Benoist (*Bulletin de la Société Française de Physique*, 91) has attempted to discover the law of transparency of substances for Röntgen rays. Defining the *specific absorbing power* as the absorption produced by a layer of unit surface density (or of 1 decigramme per square centimetre), M. Benoist finds that for ordinary rays this power increases with the density, but the results vary with the quality of the rays themselves. The author advances the view that the law of density (according to which the specific absorbing powers of all substances are equal) is a kind of *limiting* law towards which the results of observation tend as rays of higher frequency are produced.—M. Jean Perrin, in discussing the laws according to which electrified bodies are discharged (*Bulletin de la Société Française de Physique*, 93) considers that when the rays actually reach the conductor, two separate factors must be taken into account, viz. the "metal effect" produced by the incidence of the rays on the conductor, and the "gas effect" due to their action when traversing the gas. By considering the two terms separately, the law of discharge can be represented by a simple mathematical formula.—M. Désiré Korda, in the same number of the *Bulletin*, calls attention to a remarkable dissymmetry produced by Röntgen rays in vacuum tubes, and which he has observed in experiments undertaken in conjunction with Dr. Oudin.

WE have received a report of the results obtained from the experimental fields for the cultivation of the sugar-cane in Antigua, by Mr. F. Watts and Mr. F. R. Shepherd. The experiments were mainly on the advantages to be derived from the use of mineral manures in the cultivation of the cane. The remarkable and unexpected result was obtained that the addition of phosphates to the soil diminishes the yield of sugar. Nitrogen, in the form of ammonium sulphate, sodium nitrate, or dried blood, has a slightly beneficial effect on the yield; potash a much greater beneficial effect.

THE Report of the Kew Observatory Committee for the year 1896 states that the magnetic curves during the past year have been quite free from any very large fluctuations. The earthquake of December 17 was shown slightly on the Declination curve, but more distinctly on the Horizontal Force curve. The mean Westerly Declination for the year was 17° 10'·8,

and the mean Inclination 67° 22′·3. In the various experiments carried on at the observatory, particular attention has been paid to observations of atmospheric electricity, and to the comparisons of mercury and platinum thermometers. The number of instruments verified during the year exceeded 20,500.

M. Camille Flammarion brings together (*Bulletin de la Société Astronomique de France* for May) some statistics regarding the amount of rainfall in Paris since the year 1688, which discloses the remarkable fact that a gradual increase in the fall for the last two hundred years is indicated. A glance at the yearly means does not, perhaps, give such a decided apparent increase as a survey of the means obtained by grouping several years together. The following brief table, extracted from M. Flammarion's note, speaks for itself:—

	mm.
1689 to 1719	485·7
1720 „ 1754	409·4
1773 „ 1797	492·5

Whether this "increase" is actually due to more rain, or to some such causes as better positions for rain gauges, or more improved rain gauges themselves, one cannot with certainty say, but the amount of increase seems rather to negative this. The figures, nevertheless, are very astonishing; and it would be interesting to examine other series of observations extending over a long period.

The Geological Commission of Cape Colony has published a bibliography of South African geology, containing a list of nearly six hundred papers.

Astronomers will be interested to know that Mr. Henry Frowde has in hand "Tables for Facilitating the Computation of Star-Constants," by Dr. E. J. Stone, F.R.S., Radcliffe Observer at Oxford, modified and revised by Pr . H. H. Turner. We much regret to have to add to this announcement that Dr. Stone died on Sunday last.

In papers recently published in the *Bulletin* of the American Museum of Natural History (November 1896 and March 1897), Dr. J. L. Wortman makes an important contribution to the knowledge of Mammalian descent. He unites six genera of primitive Mammalia, from various horizons in the North American Eocene, into a sub-order Ganodonta, and maintains that they are the ancestors of the New World Edentates. In following one of the families of this sub-order up through successive stages of the Eocene, he finds the genealogy to be completely traceable; at the end of that period the line disappears altogether, but is taken up again in the Edentates of the Santa Cruz formation of South America. An almost inevitable conclusion from this is that about the end of the Eocene there was at least a temporary land connection between the two Americas.

Messrs. John Walker and Co., Ltd., have sent us several packets of their "Perfection Envelope," which have been designed to do away with the necessity of licking, or otherwise moistening, the gum on the flap of an envelope in order to make it adhere. The gum is placed upon the back of the envelope instead of on the flap, so that by moistening the flap the envelope can be sealed without touching the gum with the tongue. The advantage thus gained is not very clear, for it is possible in the case of any envelope to moisten the back instead of the gummed flap. What is really required is a simple device for sealing envelopes without going through the very objectionable practice of licking them.

A second edition of Prof. Lester F. Ward's "Dynamic Sociology, or Applied Social Science, as based upon Statistical Sociology and the less Complex Sciences" (two volumes) has been published by Messrs. D. Appleton and Co. The work first appeared in 1883, when there was not a chair of Sociology in any University in the world. Now there is a small army of active professors of Sociology in the United States alone, and the demand has consequently arisen for a new edition of Prof. Ward's pioneer work. Very little revision has, however, been made. An amusing story is told by Prof. Ward with reference to his volume. The book was interdicted in Russia, but the grounds upon which the action of the Russian Government was based were not clear until a correspondent suggested that the cause of trouble was the title, which appeared to be "a compound of *socialism* and *dynamite*."—A second edition of Dr. L. Edmunds' "Law and Practice of Letters Patent for Inventions" has been prepared by Dr. T. M. Stevens, and is published by Messrs. Stevens and Co. The first edition of the book appeared in 1890, and was reviewed in our columns in that year (vol. xliii. p. 53).—Prof. E. A. Schäfer's very instructive "Course of Practical Histology" (Smith, Elder, and Co.) has reached a second edition. The volume is a practical handbook in which practicable methods are described. Its aim is "to assist the student to carry on histological work independently of the constant presence of a teacher"; and well is this purpose realised throughout the book. —Messrs. E. and F. N. Spon have published a third, considerably enlarged, edition of "The Engineer's Sketch-Book," by Thomas W. Barber. The work contains 2603 sketches of "mechanical movements, devices, appliances, contrivances and details employed in the design and construction of machinery for every purpose, classified and arranged for reference for the use of engineers, mechanical draughtsmen, managers, mechanics, inventors, patent agents, and all engaged in the mechanical arts."

Among noteworthy papers and other publications which have come under our notice within the past few days are the following:—Dr. Fridtjof Nansen contributes to the *Geographical Journal* (May) a valuable outline of the scientific results obtained during the Norwegian Arctic Expedition. The same journal contains a full report of the discussion of the North Polar problem, at the Royal Geographical Society on March 22.—Mr. J. Holt Schooling illustrates "The Weight of the Earth" with several ingenious diagrams in the *Strand Magazine*.—Three books, by Prof. C. Lloyd Morgan, referring to the human mind and animal intelligence, furnish the text for an article in the *Quarterly Review* (No. 370, April).—Two papers on the structure and physical characters of striped muscular fibre, and the phenomena of its construction, appear in the *Journal of Anatomy and Physiology* (April), and form useful contributions to a subject which has for many years furnished histologists and physiologists with material for controversy.—The notes on progress in petrography, contributed during 1896 to the *American Naturalist*, by Mr. W. S. Bayley, have been brought together in a pamphlet, which should prove very serviceable for reference.—In the *Proceedings* of the Royal Society of Victoria (vol. ix.), containing papers read before the Society during 1896, are described: A new species of marsupial from Central Australia; aboriginal rock painting in the Victoria Range, County of Dundas, Victoria; geographical distribution of land and fresh-water vertebrates in Victoria; the temperatures of reptiles, monotremes and marsupials; the "Burbung" of the New England Tribes, New South Wales, and the "Bora" of the Kamilaroi Tribes (these detailed descriptions of ceremonies of Australian native tribes are based upon personal observations made by the author, Mr. R. H. Mathews); a contribution to the knowledge of the Tertiaries in the neigh-

bourhood of Melbourne; and the values of the wave-lengths of the spectrum lines of the alkalies, as determined by a new periodic formula.—A discourse pronounced by the late Dr. du Bois-Reymond in honour of the memory of Hermann von Helmholtz, is now published by Veit and Co., Leipzig. The discourse is a full and valuable statement of Helmholtz's life and scientific work.

THE additions to the Zoological Society's Gardens during the past week include an Orang-outang (*Simia satyrus*, ♀) from Borneo, presented by Lord Ashburton and the Earl of Crawford; a White-crowned Mangabey (*Cercocebus æthiops*, ♀) from West Africa, presented by Mr. Bernard A. Collins; a Malayan Bear (*Ursus malayanus*, ♀) from Malacca, presented by Lord and Lady Ashburton; a Nightingale (*Daulias luscinia*), British, presented by Mr. W. H. St. Quintin; three Common Boas (*Boa constrictor*) from the Teffe River, Upper Amazons; a Brazilian Tortoise (*Testudo tabulata*) from Brazil, presented by Mr. H. C. Fernando Rohé; a Phayre's Tortoise (*Testudo emys*) from Borneo, presented by H.H. the Tuan Muda of Sarawak; a Forsten's Lorikeet (*Trichoglossus forsteni*) from Sumbawa, a Blue-faced Lorikeet (*Trichoglossus hæmatodes*), two Perfect Lorikeets (*Psitteuteles euteles*) from Timor, a Phayre's Tortoise (*Testudo emys*) from Borneo, deposited; a Malbronck Monkey (*Cercopithecus cynosurus*, ♂) from Congoland, two Phayre's Tortoises (*Testudo emys*) from Borneo, two Long-tailed Grass-Finches (*Poëphila acuticauda*) from North-west Australia, purchased.

OUR ASTRONOMICAL COLUMN.

MAY METEORS.—During the month of May the number of meteors is by no means considerable, the records showing quite a dearth of deduced radiant points at this season of the year. One, however, which seems to be, to some extent, prominent (*Astr. Nach.*, No. 3418), is that which is situated in the region near the brightest star in Corona. The Greenwich observers in 1866 one evening recorded no less than seven first magnitude meteors, and five fainter ones, in the course of an hour; and Mr. Denning tells us that he himself made some very successful observations in 1885. This observer is of opinion that previous observations indicate the occurrence of a special shower, and he gives, as a mean of many determinations of the positions of radiant points, the coordinates $232°\cdot8 + 28°\cdot6$. May 18 is given as the day on which special attention should be devoted to this shower.

CENTRALSTELLE TELEGRAMS.—We have received a communication from Prof. H. Kreutz, in Kiel, which informs us that he has taken over definitely the direction of the Central Bureau for astronomical telegrams, and that in future the telegraphic address will *not* be Bureau der Centralstelle, Koniglichen Sternwarte, Kiel, but Astronomische Centralstelle, Kiel. Prof. Kreutz also incloses the "Statutes" of the Centralstelle, which have been recently revised.

ACCIDENTAL ERRORS OF TALCOTT OBSERVATIONS.—From a series of observations, 500 in number, made with the object of determining the latitude of Hong Kong, Herrn Doberck (*Astr. Nach.*, No. 3418) states some interesting facts about the choice regarding magnitude of stars that will be useful to observers using the Talcott method. It has been previously found that neither the zenith distance, nor the amount of the difference of zenith distance, if within 10′, affects the error of the results; neither is the difference of right ascension, if less than 20 m., affected. Herrn Doberck suggests that these limits might with advantage be extended: it is better to "observe bright stars with zenith distance greater than 20°, difference of right ascension greater than 20 m., and difference of zenith distance greater than 10′, than to observe fainter stars within these limits, as the accidental errors of observation increase when the brightness of the stars decreases." Taking the average magnitude of each pair of stars from 3·5 magnitudes up to the 7th magnitude, he gives a table showing the probable errors of one observation for each increase of half a magnitude.

FURTHER STUDIES ON SNAKE POISON AND IMMUNITY.

PROF. CALMETTE, whose name is so indissolubly associated with the study of snake bites and their treatment by anti-venomous serum, has lately published in the *Pasteur Annales*, in conjunction with his assistant M. Delarde, a most interesting and highly important series of experiments helping to elucidate the mechanism of immunity. Endeavouring to throw light upon some of the problems surrounding this highly complex question, Calmette has selected two different kinds of toxin, the one vegetable and the other animal.

The vegetable toxin was furnished by the substance known as abrine, which is the active principle of the seeds or beans of *abrus precatorius*, a leguminosa common in India and South America. It is a highly toxic material, and one milligramme suffices to kill a rabbit in forty-eight hours. Very few animals apparently can resist its action, and so far as Calmette's observations go, this immunity is restricted to hedgehogs, fowls, tortoises, snakes (*couleuvres*) and frogs. It requires as much as ten milligrammes of abrine to destroy either a hedgehog or a fowl in forty-eight hours, whilst a tortoise only succumbs after a dose of thirty milligrammes.

The animal toxin selected for these experiments was, as might be expected, serpent venom, consisting of a mixture of venoms derived from various kinds of poisonous snakes.

In the course of his previous researches, Dr. Calmette was led to believe that snakes had a charmed life against all injections of serpent venom; but he now tells us that his earlier conclusion requires correction. He has succeeded in killing Egyptian asps and a serpent native to Indo-China by injecting doses of venom three times as great as that normally present in their respective poison glands, and he is, therefore, of opinion that although reptiles do possess great powers of resisting the toxic effect of serpent venoms, yet, contrary to what he at first supposed, their immunity to this poison is not absolute.

Various hypotheses have been suggested to account for this comparative immunity exhibited by reptiles to the effect of venom, and Prof. Fraser, of Edinburgh, has attributed this phenomenon to the presence in the blood of reptiles of some anti-toxic substance. Calmette, however, has shown that, far from protecting animals from the toxicity of venom, reptile blood causes their death. Experiments in this direction were not only made with the blood derived from the liver and other organs of a *naja tripudians*, but also with injections of a filtered aqueous emulsion of these organs, but in no case was any protective action recorded.

Again, the serum of pigs, which animals in some countries are specially trained for the purpose of hunting serpents, which they devour greedily without suffering the least inconvenience from their bites, the serum of these animals has no modifying action whatever outside the body, *in vitro*, on serpent venom, and has no protective action.

Similar experiments were also made with animals exhibiting a relative immunity to the toxic action of the vegetable poison, *i.e.* abrine. It was found that whereas the normal serum of hedgehogs, which animals possess a natural immunity to abrine poisoning, can protect other animals susceptible to this toxin from its lethal effects, yet to do so effectually large quantities of the serum in question must be employed. On the other hand, fowls and tortoises, although also naturally immune to the abrine toxin, can confer, by means of their serum, no protective power whatever upon other animals against this poison.

The next question approached by Calmette was whether these so-called refractory animals can elaborate anti-toxins, and in the course of his experiments on this subject he obtained some very curious results.

For these investigations abrine only was employed, and profiting by the fact that fowls and tortoises had proved very refractory to this toxin, these animals were chosen as subjects for the inquiry.

Two fowls were given, in the course of twelve days, about eight milligrammes of abrine. Whilst, as we have seen, ordinary fowl-serum can confer no immunity from the effects of abrine poison, the serum derived from the abrine-treated fowl was possessed of immunising properties. In this case, therefore, a refractory animal, normally incapable of yielding an anti-toxic serum, had been trained by artificial means to do so. Similar experiments made with another refractory animal gave, however, quite different results, for when tortoises were treated with abrine poison, instead of their serum acquiring any protective

property, it killed those animals into which it was injected, and by no amount of artificial training could their serum become endowed with any immunising effect. Exactly similar results were obtained with frogs, and whilst the normal blood of these animals was repeatedly proved to be quite devoid of all toxic action on mice, yet after the frogs had been inoculated with abrine, and trained to acquire an immunity beyond their brother frogs towards this substance, their blood invariably killed the mice into which it was injected. Dr. Calmette concludes from these observations that natural immunity to a particular toxin does not imply the existence of a specific anti-toxic substance in the blood of such refractory animals, and that whilst apparently warm-blooded abrine-refractory animals can be trained to elaborate anti-toxins, cold-blooded abrine-refractory animals cannot produce such anti-toxins in the normal conditions of their existence. The latter portion of this generalisation receives some support from Metchnikoff's observations of the same phenomenon in the case of tortoises and tetanic-toxin.

Prof. Calmette next proceeds to discuss the properties of serum derived from those animals in which the immunity to a particular toxin is not natural, but has been artificially induced. We are again for this purpose taken back to anti-venomous serum, and some additional information is given incidentally of the wonderful efficacy which characterises this remarkable remedy for snake bites. Perhaps one of the most astonishing properties of this serum is the rapidity with which it operates. Thus if two cubic centimetres of anti-venomous serum be inoculated into the marginal vein of a rabbit's ear, it at once confers upon the latter immunity towards snake poison. Immediately after the injection of the serum, venom sufficient to destroy an ordinary rabbit in a quarter of an hour may be injected with impunity into the vein of the other ear. Its degree of therapeutic efficiency is also extraordinarily intense, as is well illustrated by the following experiment: four rabbits are inoculated with a quantity of venom sufficient to destroy them in two hours; one of these is left, whilst the other three receive, one hour and three-quarters later, an intravenous injection of serum equal in quantity to one four-hundredth part of their weight. Whilst the unprotected rabbit dies in two hours, the other three remain in perfect health. "Voilà donc un sérum qui," writes Calmette, "d'emblée, sans reaction préalable de l'organisme, produit l'insensibilisation absolue des cellules à l'égard du venin."

Of great importance in their practical bearing are the experiments which are recorded on the *local* action of anti-abrine and anti-venomous serum respectively. As is well known, abrine was at one time used for the treatment of trachoma, but unfortunately the subsequent suppuration which attended its use was in many cases so intense and so dangerous that it had to be abandoned for therapeutic purposes.

Now Calmette has found that by applying anti-abrine serum to the local parts affected, the inflammatory action of abrine is modified in a very remarkable manner, and the hope is held out that by using this serum, and so controlling the inflammation induced by the application of abrine, this valuable substance may once more be reinstated in the therapeutics of ophthalmology. Anti-venomous serum has apparently the same local immunising action as the anti-abrine serum.

Another practical point of great importance concerning these serums is also dealt with in detail; this is the diagnostic value attaching to their use. Already Pfeiffer and other investigators have shown how, by means of serum, it is possible to differentiate between cholera and other non-pathogenic vibrios, and to distinguish the typhoid from the closely-allied *B. coli communis*. A most interesting opportunity occurred for testing the diagnostic power of anti-venomous and anti-abrine serums respectively. In India the natives frequently wreak their vengeance on their enemies by poisoning their domestic animals, and the substances selected for this purpose are those which they know will be with difficulty detected by expert analysis. Two materials are specially favoured by them for this purpose, *i.e.* abrine and serpent venom. One method of administering the poison consists in taking short pieces of wood shaped in the form of a club, in the thick end of which small-pointed rods are carefully fitted. These rods are composed of a hard greyish-looking substance. Armed with these tiny clubs, which they can easily conceal in their hands, they inflict small scratches, scarcely visible, upon the cattle, but in the production of which the pointed end of the little rod is broken off, and in this manner the cattle become inoculated with the poison. Some of these small broken-off points were sent by Mr Hankin, of Agra, to Dr. Calmette for examination. On dissolving these fragments in water and inoculating the liquid into rabbits, the latter died, exhibiting the symptoms typical of abrine poisoning. The same quantity of this liquid mixed with some anti-abrine serum produced no toxic result whatever. Thus Dr. Calmette considers his diagnosis of the poison employed as being abrine fully justified. In a somewhat similar manner the use of serpent venom was also detected.

These results open up a new avenue to the physiological detection of toxins, whether of animal, vegetable, or bacterial origin by means of serums.

Some extremely interesting experiments were also made to ascertain whether toxins and antitoxins were capable of modifying one another outside the body *in vitro*. The following examples give some idea of the results obtained. 5 cubic centimetres of anti-venomous serum were mixed *in vitro* with 4 milligrammes of cobra venom, and this mixture was injected intravenously into a rabbit. The animal remained unaffected; at the end of an hour, this same rabbit was again intravenously inoculated with 1 milligramme of venom. It died thirty-five minutes afterwards. Thus although its death was slightly deferred beyond that which was noted for the control animal, yet it succumbed almost as readily as if it had received no protective serum whatever. Again, 5 cubic centimetres of anti-venomous serum were mixed with 4 milligrammes of venom and 1 cubic centimetre of a 10 per cent. solution of hypochlorite of lime, and the whole was inoculated into a rabbit. This same animal, on subsequently receiving a dose of venom usually fatal, suffered no ill-effects at all. In this case, Dr. Calmette points out, that whilst the serum had remained unaffected by the addition of a chemical substance, the toxic nature of the venom had, on the contrary, been entirely destroyed. Hence it is claimed that when toxins and their anti-toxins are mixed *in vitro*, the former do not appear to undergo any change or modification through the presence of the latter. Therefore, either these substances can remain side by side outside the body intact, or, if any combination between them does occur under these circumstances, it is a combination which is so unstable that the application of heat or various chemical substances is able to easily bring about their disunion, restoring to either the properties they possessed before being brought into contact. Dr. Calmette, in concluding his most valuable memoir, records a large number of experiments made to ascertain what is the degree of protective power exercised by anti-toxic serums of different origin and certain liquids on animals inoculated with abrine. It has been found that broth freshly prepared, normal ox-serum, anti-tetanic serum, anti-diphtheritic serum, anti-anthrax serum, and, above all, anti-cholera serum, exert individually a decided immunising action with regard to abrine. Although the protective action of these so-called foreign serums is not so pronounced as in the case with anti-abrine serum, yet they do most undoubtedly confer a certain degree of protection. Dr. Calmette considers that this artificially induced immunity must be regarded as a condition in which the cells of the body are specially stimulated, and are thus enabled to either temporarily or permanently resist the action of particular poisons.

The mechanism of immunity will not permit itself to be lightly mastered, and it is only by the conduct of painstaking and patient inquiries, of which those just described are such a splendid example, that a comprehension of this most important as well as fascinating phenomenon can ever be hoped for.

ON THE VARIATION OF LATITUDE.[1]

AT the autumn meeting of the National Academy in 1894, which was the last occasion upon which the author asked for its attention to this subject, he presented the numerical theory of the motion of the pole, synthetically derived from the observations from the beginning of the history of the astronomy of precision up to that time, in its complete development, exactly as it stands to-day. Since then he has been interested to compare it with the various series of observations, as they have been published from time to time, not only for the purpose of verification or improvement of the numerical values of the various constants, but also to detect any additional characteristics which these later data might make apparent. These additional investigations have individually been neither extensive nor important enough to call for separate publication; since their general result has been merely a satisfactory confirmation of the

1 Abstract of a paper read before the National Academy of Sciences at Washington, April 21, by Prof. S. C. Chandler.

previous deductions as to the nature of the laws of these motions, without furnishing material improvement of the numerical elements. But sufficient material has thus been gradually accumulating to make the present communication of some interest.

The new material to be here utilised consists of the various series of observations by Tallcott's method up to the middle of 1896, as far as published, at the following European stations, named in the order of longitude: Kasan, Vienna, Prague, Berlin, Potsdam, Karlsruhe, and Strasburg. America has Doolittle's series at Bethlehem, which was brought to an end in the summer of 1895. He is now carrying forward a new series at Philadelphia, of which the results may soon be expected. Of the series at Columbia University, by Rees, Jacoby and Davis, begun in the spring of 1893 and still current, the results for the first fourteen months came into the author's hands a few days ago, so that he was able to incorporate them in his investigations.

The curves of latitude-variation from these various series were then exhibited, and comparisons made with the known numerical theory. This shows a concordance and fidelity of representation which is in every way satisfactory, the difference between computation and observation being practically within the range of the uncertainty of errors of observation.

A determination of the elements of the ellipse of the annual component of the polar motion was then presented, made from the new observations independently of the older ones previously used. The resulting elements are practically identical as to form, size, and position. This seems to show that the axis of this elongated vibratory motion is stationary on the earth's surface along a meridian forty-five degrees east of Greenwich. This negative evidence as to any apsidal motion seems to be of extreme importance in its bearing on the theory of the earth's rotation.

A demonstration was then presented of the fact that since 1890 the circular 428-day motion has been diminishing its radius, in conformity to the requirements of the numerical theory derived from the observations from 1825 to 1890.

In addition to the above, a discussion of 718 observations of the Pole-star, made with the Pulkova vertical circle between 1882 and 1891, was given. This series is especially interesting and important in that it covers an interval during which we have very little other information, of an extended character, as to the variations of latitude. A comparison of the curves of observation and theory, thus provided for this decade, exhibited the most startling accordance, and seems to leave no possible doubt that Nyren's inference, that his observations do not betray evidence of the existence of the annual component of the polar motion, is erroneous and attributable to illogical methods in drawing his conclusions.

TECHNICAL EDUCATION IN LONDON.

THE work of the Technical Education Board of the London County Council has been favourably commented upon in these columns on many occasions. The Board includes among its members several well-known educationists; and in its Secretary, Dr. W. Garnett, it possesses an official whose knowledge of science makes him capable of taking a wide view of things, and of seeing the best and most practicable lines of development of technical education. The fourth annual report of the Board, presented to the Council on Tuesday, is a substantial testimony of work accomplished during the year ending with March. To do the report justice would take many columns of NATURE, but brief references to a few of the operations of the Board will, perhaps, suffice to give an idea of the valuable and extensive character of the work carried on.

The Board has continued its policy of attempting primarily to coordinate and develop the provision for technical education made by the various public institutions of the metropolis. By its grants of money, no less than by the expert assistance which it has placed at the disposal of the various governing bodies, the technical work of these institutions has been greatly extended during the past year. There are now no fewer than ninety-eight separate institutions in London to a greater or less extent supported by the Board, and inspected by its officers.

Special attention has been paid to developing and improving the instruction provided for apprentices, improvers and journeymen in the principal London industries. There are now more than two hundred well-equipped and efficient centres of definitely practical instruction in various trades. The character of the instruction given differs slightly, but, on the whole, it is of a kind that will assist industrial progress. As to instruction in electrical engineering, it is a noteworthy fact that from sixteen to eighteen students from the Royal College of Science have been attending the evening classes for electrical engineers at the South-West London Polytechnic Institute. This may be taken as good evidence of the Polytechnic's efficiency.

London now has eleven polytechnic institutions, which have on their rolls probably not fewer than 40,000 separate members or students. Nearly all the polytechnics provide instruction in science, art, technology, commercial subjects, literary subjects and domestic economy, and during the session 1895-96, before the Northampton Institute and the Northern Polytechnic were opened, the students registered at the London polytechnics, including the People's Palace and the Goldsmiths' Institute, in the several departments, were—

Science	8371
Art	2910
Technology	4692
Domestic economy	2678
Commercial subjects	8244
Total	26,895

The eleven polytechnic institutes referred to may be estimated for the current session 1896-97 to be spending in all their departments a total of about 128,000*l.* per annum, of which, roughly speaking, 29,000*l.* will probably be provided by the City Parochial Trustees, 25,000*l.* by the Technical Education Board, 22,000*l.* from City Companies, 12,000*l.* from private subscriptions and other endowments, 9000*l.* from Government grants, and 30,000*l.* from students' fees, &c. The total capital expenditure can only be roughly guessed at, but it will certainly have exceeded 500,000*l.* They may be expected to have in 1897-98, a total of about 45,000 separate students in all subjects, as compared with a corresponding total for 1892-93 of probably not more than 20,000.

The development of the higher departments at several of the polytechnics has during the last two or three years greatly increased the provision of higher instruction, especially in engineering, chemistry and physics. In the new and well-equipped laboratories now provided at these institutions by means of the Board's equipment grants, facilities are given for the student to pursue his work, without a break, from the elements of the subject up to the highest branches, and to undertake, in conjunction with his teacher, original investigation and research. A considerable addition has thus been made to the instruction of distinctly university rank now accessible to the London student, and it is estimated that, in addition to a large number preparing for matriculation, there are now over one hundred matriculated students in the polytechnics who are definitely studying for London university degrees in science. This number constitutes no small proportion of the total of matriculated students for science degrees, other than those in the medical schools, who are studying in organised educational institutes in London.

This great development of instruction of university rank in new institutions has increased the importance of bringing about a more systematic coordination of university education in London. The Board has accordingly continued to press for the early establishment of the promised new Teaching University for London, towards the technical departments of which it was proposed in Mr. Llewellyn Smith's report that the Board should contribute. The establishment of a well-endowed Teaching University for London, which should effectively coordinate and direct all the teaching of university rank that is now scattered about the metropolis, would probably do more than anything else to promote technical education. When this university will be established, it would be unwise to guess. Meanwhile the Board has attempted to bring about more coordination between the different institutions providing university instruction in technical subjects, and arrangements are in progress for courses of inter-collegiate lectures, mainly in post-graduate and specialist subjects, which will be open to all students of the various institutions concerned.

An interesting map, showing the places of residence of the thousand junior county scholars elected by the first four competitions of the Board, in the years 1893-95, accompanies the report. The map shows that the scholars were distributed with fair uniformity about the whole area of the county of London.

THE MANUFACTURE OF CARBORUNDUM AT NIAGARA FALLS.[1]

THE first carborundum furnace consisted of an iron bowl lined with carbon, and a carbon rod; a mixture of clay and carbon was introduced into the bowl, and the rod placed in the mixture. A current sufficient to fuse the mixture, or at least to bring it to a very high temperature, was now passed through the furnace, the iron bowl and carbon rod serving as terminals or electrodes. When the current was cut off, and the furnace had cooled down, it was opened, with the result that a few bright blue crystals were found surrounding the carbon rod.

The furnaces constructed after this first experiment approached more nearly in form the furnaces in use to-day. They were built of brick, their internal dimensions being 10 inches in length, 4 inches in width, and 4 inches in depth. The terminals were a pair of carbons, which could be moved longitudinally, thus permitting the distance between them to be altered at pleasure. These were essentially arc furnaces; that is to say, the idea was to form an arc between the terminals, and to bring about the necessary chemical changes by the high temperature thus produced. It was soon found, however, that this method of working was not satisfactory, and the incandescent furnace, which is the kind that is now adopted, was therefore constructed.

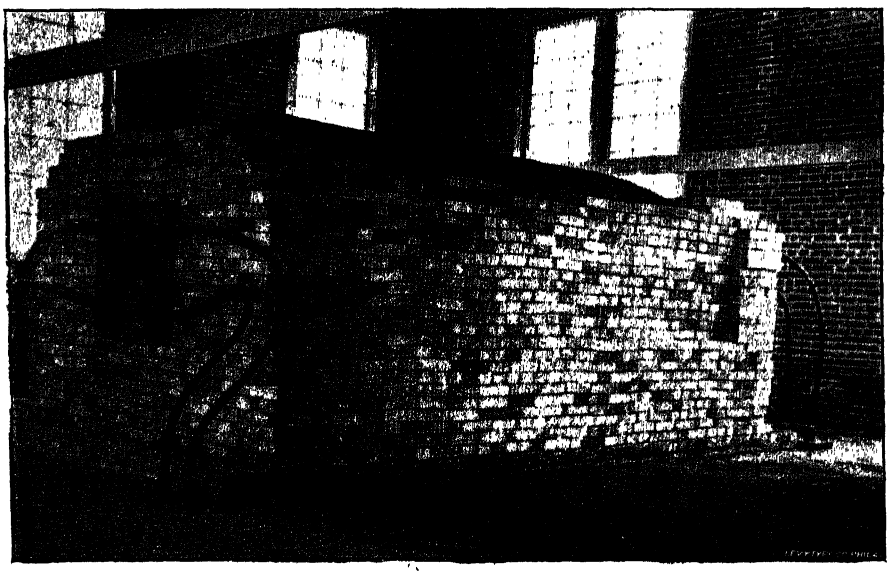

FIG. 1.—Carborundum furnace ready for operation.

Into furnaces of this kind a core consisting of granulated coke, which forms a continuous electrical connection between the carbon terminals, is introduced. By adjusting the diameter of the core to the proper size, it is heated to a sufficiently high temperature, by the passage of the current, to convert the surrounding mixture into carborundum.

It was at first supposed that the crystals formed in the furnaces were a compound of aluminium and carbon, but it was soon found that the amount and quality of the carborundum depended on the amount of silica present in the mixture. A good glass sand was, therefore, substituted for the clay in the mixture. It was also found that the addition of a little salt to the mixture facilitated the running of the furnaces. Some trouble was experienced from the gases formed during the running of a furnace, and to lessen this, sawdust was added to the mixture to render it porous, and to allow the free escape of the gas. The output of these small furnaces amounted to about a quarter of a pound a day.

The crude materials for the manufacture of carborundum at Niagara Falls are sand, coke, sawdust, and salt. These are ready for immediate use, with the exception of the coke, which must be reduced to kernels of a certain size, to be used as "core," and ground to a fine powder, to be used in making the mixture or charge for the furnaces. The furnaces are built of brick, and have the form of an oblong box, the internal dimensions being, approximately, 16 feet in length, 5 feet in width, and 5 feet in depth (Fig. 1). The ends are built up very solidly, with a thickness of about 2 feet. In the centre of either end are the terminals, consisting of sixty carbon rods 30 inches long and 3 inches in diameter. The outer ends of the carbons are enclosed in a square iron frame, to which is screwed a stout plate, bored with sixty holes corresponding to the ends of the carbons. Through each of these holes is passed a short piece of ⅜-inch copper rod, fitting tightly in a hole drilled in the carbon. Finally, all the free space between the inside of the plate and the ends of the carbons is tightly packed with graphite. Each plate is provided with four projections, to which the cables conveying the current may be bolted. These ends are the only permanent parts of the furnace; the remainder is built up every time the furnace is operated.

The side walls of the furnace are first built up to a height of about 4 feet. Pieces of sheet iron are then placed at a distance of about 4 inches from the inner ends of the carbon terminals in such a way as to keep the mixture from coming in contact with the latter. The mixture is then thrown into the furnace until it is rather more than half full. A semicircular trench, having a radius of 10½ inches, and extending from end to end of the furnace, is now formed, the bottom of the trench being a little above the level of the bottom row of carbons. Into this trench is introduced the core, which has been carefully weighed, so that the amount required to make the core of the right size is used. All the core having been emptied into the trench, the top is rounded off neatly by hand, so that, when finished, we have a solid cylinder 21 inches in diameter and about 14 feet long, composed of small pieces of coke, and extending from the sheet iron plates at either end of the furnace.

The next operation is to make the connections between the core and the terminals. This is done by packing finely-ground coke into the spaces between the ends of the carbons and the pieces of sheet iron, after which the walls are built up to a height of about 5 feet, the pieces of sheet iron removed, and more mixture thrown in and heaped up to a height of about 8 feet.

All that is required now to make carborundum is the electric current. The current as supplied from the Niagara Falls Power Company has an electromotive force or pressure of 2200 volts, so that in order to use it in the furnaces it must be transformed to a lower voltage. The transformer at the Carborundum Works has a maximum capacity of 830 kilowatts, or about 1100 horse-power, and transforms the 2200-volt current into one of only 185 volts. Associated with the transformer is a regulator, by means of which the current from the former can be raised to 250, or lowered to 100 volts.

After the circuit has been closed in the transformer-room, no apparent change occurs in the furnace for about half an hour. Then a peculiar odour is perceived, due to escaping gases, and when a lighted match is held near the furnace walls the gas ignites with a slight explosion. When the current has been on for three or four hours, the side walls and top of the furnace are completely enveloped by the lambent blue flame of carbon monoxide gas, formed by the combination of the carbon of the coke with the oxygen of the sand. During the run of a single furnace 5½ tons of this gas are given off. At the end of four or five hours the top of the furnace begins to subside gradually,

[1] Abridged from a paper by Mr. Francis A. Fitzgerald, in the *Journal* of the Franklin Institute, February 1897.

fissures form along the surface, from which pour out the yellow vapours of sodium. Occasionally, the mixture on the top of the furnace is not sufficiently porous to allow the rapid escape of the gases. The result is, that the latter accumulate until the pressure is so great that, at some weak point in the mixture above, a path is forced open and the gases rush out violently. It is mainly for the purpose of avoiding this "blowing" that the sawdust is put in the mixture, since the former, by making the mixture porous, allows the gases to escape freely.

At the end of about twenty-four hours the current is cut off from the furnace, and it is allowed to cool for a few hours. Then the side walls are taken down and the unchanged mixture raked off the top of the furnace, until the outer crust of amorphous carborundum is reached. This crust is cut through with large steel bars, and can then be easily removed from the inner crust of amorphous carborundum. The inner crust is next removed with a spade, and the crystalline carborundum exposed.

A cross-section of a carborundum furnace presents an interesting and beautiful appearance (Fig 2). In the centre is the core, which, on examination, is found to be very different in some of its physical characteristics from the coke of which it was originally composed. It no longer possesses a bright metallic appearance. Many of the kernels are quite soft, and can be squeezed between the fingers, leaving on them a mark like black lead. In fact, the high temperature to which the core has been raised has driven off all impurities from the coke, leaving nothing but pure carbon, either in the amorphous or graphitic form. From the core radiate beautifully-coloured carborundum crystals to a distance of 10 or 12 inches. A single furnace yields over 4000 pounds of crystalline carborundum. Most of these crystals are not remarkable as regards their size, but in places where hollows have formed, large hexagonal crystals are found, sometimes measuring ½ inch on a side. At the distance of 10 or 12 inches from the core the crystals suddenly cease, and, instead, we find a thin layer of a light-green colour, which is the inner crust of amorphous carborundum. Beyond this is the outer crust of amorphous carborundum, and this also ends abruptly in unchanged mixture. Other curious substances are sometimes produced in the furnaces; for example, silica, which has the appearance of spun glass. On opening a furnace and cutting down to the core, a layer is found that appears at first sight to consist of very dull black carborundum crystals. On closer examination, however, it is found that though this material has the exact form of the carborundum crystals, it is nothing but pure carbon in the graphitic form.

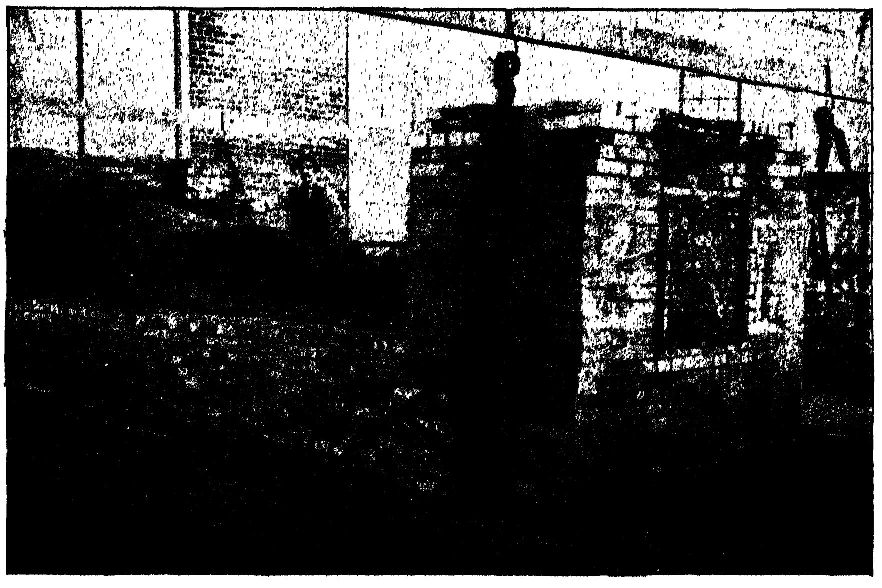

FIG. 2.—Furnace opened to show formation of carborundum around the core.

After the carborundum has been removed from the furnace it is taken to a crusher, which consists of a large iron pan, rotated in a horizontal plane by means of a vertical shaft. A horizontal shaft, carrying two heavy rollers, is attached to a collar surrounding the vertical shaft, thus permitting a free vertical motion of the rollers which rest in the pan. The latter, in revolving, causes the carborundum to pass under the rolls, which break the mass of crystals apart. From the crusher the carborundum is taken to large wooden tanks, where it is treated for several days with dilute sulphuric acid to remove impurities. It is then thoroughly washed, dried, and graded.

Carborundum is apparently infusible; for after a certain temperature has been reached, decomposition commences, without fusion, and the crystals are broken up into carbon and silicon. It is quite insoluble in water or any acid. Its hardness lies somewhere between 9° and 10°, probably very close to 10°, which is the hardness of diamond. An attempt was made to obtain some idea of the relative hardness of diamond, corundum, and carborundum, by the following experiment.

A series of lines was scratched on a small plate of glass with each of the three materials, and the scratches examined with a microscope. The appearance of the lines made by the diamond and the carborundum crystal was indistinguishable; but that made with the piece of corundum was quite different, being rough, and not presenting the clean-cut outlines of the other scratches. This seems to show that carborundum is much nearer diamond than corundum in hardness, although it is not as tough. The specific gravity of carborundum is 3·23, which is less than that of emery, 1¼ pounds of the latter being equal in volume to 1 pound of the former.

Carborundrum is chiefly used at present as an abrasive, for which purpose it possesses many advantages over emery and corundum. The Carborundum Company produced during the year 1896, in round numbers, 1,191,000 pounds of crystalline carborundum.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Prof E. B. Elliott and Prof. H. H. Turner have been appointed Electors to the Savilian Professorship of Geometry.

The Board of the Faculty of Natural Science have given notice that henceforth in the Final Honour School of Chemistry the use of books in the examination in Quantitative Analysis, and in any part of the examination, shall be at the discretion of the Examiners.

Trinity College has decided to build a laboratory adjoining the existing laboratory of Balliol College, and communicating with it. Such action in favour of Oxford science on the part of a College, far from rich, is especially commendable.

This term Mr. H. H. Champion, of Cambridge, is lecturing, for Prof. Turner, on "Lunar Theory." Prof. Ray Lankester will lecture on Arthropoda, and Mr. G. C. Bourne on Mechanical Theories of Development. Dr. Benham and Mr. Bourne are conducting the annual summer course of Practical Embryology.

Prof. E. B. Tylor's subject for this term is the Anthropology of Political and Social Institutions. Mr. Barclay Thompson

announces courses on Mammalian Morphology and Palæontology. The usual courses are being given in the departments of Physics, Chemistry, Mineralogy and Botany and Physiology.

In the Faculty of Medicine, Dr. Ritchie, Lecturer on Pathology, will give a course of practical instruction on Bacteriology. Lectures will also be given on Medicine, Surgery, and Materia Medica. Prof. Arthur Thomson is lecturing on the Uro-genital system.

April 13 being the twenty-fifth anniversary of the Zoological Station at Naples, Dr. Anton Dohrn sent a telegraphic message to the Chancellor, acknowledging the assistance rendered by the University to the Station.

Prof. Burdon Sanderson has been re-elected Chairman of the Board of Faculty of Medicine.

The large and valuable collection of butterflies offered to the Hope Department of the University by Mr. F. Ducane Godman, F.R.S., and Mr. Osbert Salvin, F.R.S., was accepted by Convocation on Tuesday, and the thanks of the University were voted to the donors. The collection has already been briefly described in NATURE (vol. lv. p. 524, April 1).

CAMBRIDGE.—A memorial, signed by 2100 resident undergraduates and bachelors of arts, has been presented to the Vice-Chancellor, protesting against the proposal to grant titles of degrees to women, on the ground that this would injure the position and efficiency of the University as a University for men. A counter memorial, signed by only 298 of the junior members of the University, has also been received. It states that in the opinion of the signatories the proposal would *not* injure the University. Meanwhile the notice of *non-placet* by the resident graduates has been circulated, and bears the names of about 280 members of the Senate, out of about 450 in actual residence. The list includes eighteen professors and 110 past or present tutors and lecturers. If, therefore, the decision lay with the resident body of teachers and officers, the result would be a decided negative; and there is no doubt that among the students the feeling against the contemplated change is overwhelmingly strong. The latter fact gives some colour to the assertion that the admission of women would probably be followed by a serious falling off in the number of men desirous of entering the University.

The proposal of the Special Board for Physics and Chemistry, that candidates for either part of the Natural Sciences Tripos should be required to submit to the Examiners their laboratory note-books, duly attested by the signatures of their teachers, has been adversely criticised in the Senate. It was feared that it might interfere with the good relations at present existing between teachers and students, and encourage the special preparation of note-books for the Examiners' inspection. The Report was referred back to the Board for reconsideration.

The dates of the next ensuing College Examinations for Scholarships and Exhibitions in Natural Science are announced as follows:—November 2: St. John's and Trinity, Pembroke, Caius, King's, Jesus, Christ's, and Emmanuel. November 30: Peterhouse and Sidney Sussex. December 7: Clare and Trinity Hall. April 1898: Downing. Information as to the value and conditions of tenure of the several emoluments may be obtained from the respective College Tutors.

WE understand that the late Prof. Edward D. Cope left an estate valued at over one hundred thousand dollars. Most of the amount is bequeathed to the University of Pennsylvania, and to establish a chair of Vertebrate Palæontology in the Philadelphia Academy of Natural History.

AMONG the grants just authorised by the legislature of the State of New York are: 2,500,000 dols. for the new public library in New York City; 500,000 dols. for an extension of the Museum of Natural History; 150,000 dols. for the new Zoological Park in New York City; and 10,000 dols. for the proposed public library in Brooklyn.

In a brief note (p. 21) on the application of the Hartley Institution for a share of the increased grant which it is proposed to give to the University Colleges of Great Britain, the term "professorial" staff was misprinted "professional" staff. Dr. R. W. Stewart, the Principal of the Institution, calls our attention to the fact that the Committee appointed to consider the distribution of the Government grant gave, in 1889, what almost amounted to a pledge that if certain defects in the Institution were remedied, a future application for a share of the grant might receive favourable consideration. The work and management of the Institution have since then been entirely reorganised, and it is on these grounds that the application has been renewed.

THE following are among recent appointments:—Dr. C. H. Draper to be head-master of the Municipal Technical School at Brighton; Miss M. Maclean to be demonstrator of anatomy, and Miss D. Clark demonstrator in the botanical laboratory, in Queen Margaret College, Glasgow; Mr. W. H. Lang to be lecturer on botany in the same college; Dr. Frech to be professor of geology and palæontology at Breslau; Dr. Walter Kruse to be professor of hygiene at Bonn; Dr. W. Ule to be professor of geography at Halle; Dr. Gustav Jäger, privat-docent in theoretical physics at Vienna, to be a professor; Prof. W. F. Edwards to be president of the Washington University, Seattle; Dr. Andr. Lipp to be professor of analytical chemistry in the Polytechnic Institute at Munich. Prof. Sissingle, of the Polytechnic Institute of Delft, has been called to the chair of Physics in the University of Amsterdam.

THE Technical Education Board of the London County Council will proceed shortly to award not less than five Senior County Scholarships, which are of the value of 60*l*. a year, together with payment of tuition fees up to 30*l*. a year, and are tenable for three years at university colleges and advanced technical institutes. These scholarships are confined to residents within the administrative county of London, and are only open to those whose parents are in receipt of not more than 400*l*. a year. Candidates should, as a rule, be under twenty-two years of age, though the Board reserves the right to give preference to candidates who are under nineteen years of age. The scholarships are intended to encourage more especially the teaching of science, and to enable those students who cannot afford a university training to pursue advanced studies for a period of three years in the highest university institutions in the country. Candidates must apply before Monday, May 17, to the Secretary of the Technical Education Board, St. Martin's Place, W.C.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. xix. No. 2 (April 1897).—On the most perfect forms of magic squares, with methods for their production, is an interesting paper on these squares by Dr. E. McClintock, which treats the subject in a somewhat novel manner. As it was read before the American Mathematical Society so long ago as April 25, 1896, the references to the Rev. A. H. Frost's work on similar lines make no allusion to the recent memoir by this gentleman (the construction of Nasik squares of any order), which was read before the London Mathematical Society, June 11, 1896, and, in its printed form, occupied pp. 487–518 of vol. xxvii. of the Society's *Proceedings*. Dr. McClintock refers to the earlier papers in the *Quarterly Journal of Mathematics* (vol. vii. and xv.).—Dr. Chree contributes a complementary paper to his article in vol. xvi. Its title is "Isotropic elastic solids of nearly spherical form." The method of the two papers is practically the same, but the author states the differences in detail to be considerable. His principal object is to find what may be regarded as the change in pitch due to a small change in the shape of the surface; the result shows what effect an absence of perfect sphericity has on the frequency of vibrations.—Non-uniform convergence and the integration of series, term by term, by W. F. Osgood, is a paper which was read at the August (1896) meeting of the American Mathematical Society. The geometrical method for the study of uniform convergence, set forth in the present article, was treated at some length in a paper by the same writer, which we have noted in our abstract of the Society's *Bulletin* (vol. iii. pp. 59–86) for November 1896.—Two notelets close the number: viz. a note on the factors of composition of a group, by Ellery W. Davis, and simple proof of a fundamental theorem in the theory of functions, by R. D. Bohannan.—A loose sheet gives a very brief outline of Sylvester's career and work. Prof. Sylvester was the principal founder of the *American Journal of Mathematics* (in 1877), and he was the principal editor until his departure from America in December 1883. He contributed to its pages some fifty papers in all.

Bulletin of the American Mathematical Society, vol. iii. No. 7 (April 1897).—On Cayley's theory of the absolute, is a paper by Prof. C. A. Scott, which was read at the January (1897)

meeting of the Society. Miss Scott attempts to show, "as a matter of purely pedagogic interest," how simply and naturally Cayley's theory follows from a small number of very elementary geometrical conceptions, without any appeal to analytical geometry. Lines common to four linear complexes, is a short note, by Dr. V. Snyder, which was read at the February meeting.—The cubic resolvent of a binary quartic derived by invariant definition and process, by Prof. H. S. White, was read at the Chicago Conference (January 1, 1897).—Dr. Isabel Maddison reviews two recent works on geometry, viz. Phillip's and Fisher's "Elements of Geometry," and H. D. Thompson's "Elementary Solid Geometry and Mensuration," which she thinks rise above the general level. Dr. Maddison also points out that the map-colouring problem was discussed (before Cayley and De Morgan wrote upon it) by Möbius, in his lectures in 1840. The problem was propounded to Möbius by Prof. Weiske, and is to be found in the *Berichte der Sächsischen Gesellschaft der Wissenschaften zu Leipzig*, Math.-physiche Classe, Bd. 37, 1885. The Note referred to is by Prof. Baltzer, and its title is "Eine Erinnerung an Möbius und seinen freund Weiske."—The Notes contain the mathematical courses at the Universities of Berlin and Harvard.

THE last number of the *Journal of the Russian Chemical and Physical Society* contains, in an appendix, the third instalment of the "Record" (*Vremennik*) of the Russian Chief Board of Measures and Weights. Most of it is given to an elaborate paper, by Prof. Mendeléeff, on the "Methods of Accurate or Metrological Weighings." The formulæ relative to the oscillations of the scales' index, and to the "condition" of the scales, are discussed in great detail, and new formulæ are given; while the discussion of some of the results has brought the Russian professor to the discovery of a new property of the parabola relative to the surface of a segment of it (*Comptes rendus*, 1895, p. 1467).—The same issue contains papers on the quantity of carbon dioxide contained in the air of the Weighing Hall of the Board of Measures and Weights, by A. Dobrokhotoff; the results of the verification at the Standards Department of the Board of Trade, in 1894 and 1895, of the Avoirdupois Pound belonging to the Russian Government, and the comparison of the Russian half-sashen with the Imperial standard yard, by H. J. Chaney, Mendeléeff, and Blumbach (in English and Russian); on the geographical position of the Board of Measures (chiefly its exact altitude above the sea-level); and a note, by Prof. Mendeléeff, on the agreement of the author's well-known formula for the density of water at different temperatures with the last measurements of the same, by M. Thiesen.

Bollettino della Società Sismologica Italiana, vol. ii., 1896, N.N. 7, 8.—Influence of the different nature and sensitiveness of instruments on the measure of the velocity of seismic waves, by G. Agamennone.—On the geodynamic system of the world, by G. Grablovitz.—Summary of the principal eruptive phenomena in Sicily and the adjacent islands during the six months July–December 1896, by S. Arcidiacono.—Velocity of propagation of the earthquake of Ahmed (Asia Minor) of April 16, 1896 (in French), by G. Agamennone.—Vesuvian notes for the year 1896, by G. Mercalli.—Notices of earthquakes recorded in Italy, August 31–September 8, 1896; the most important being a series of records of the Iceland earthquake of September 6.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 8.—"Further Note on the Sensory Nerves of Muscles." By C. S. Sherrington, M.A., M.D., F.R.S., Holt Professor of Physiology in University College, Liverpool. Received February 26.

I was somewhat surprised when, after the sensory nature of the structures originally termed muscle-spindles (Kühne) had been proved (Sherrington), I was unable to find in the eye-muscles any examples of these structures. I had expected to find in those muscles, on account of the great delicacy of their control and coordination, and in view of the well-known richness of their innervation, a field peculiarly favourable for the examination and study of "spindles."

I had noted that the intrafusal muscle-fibres, of the "red" variety as they are, undergo, when the nerve-trunk of a muscle has been severed, a much slower course of alteration than do extra-fusal muscle fibres, *i.e.* I found no pronounced degeneration for even two years following section. I therefore cut through *n. oculomotorius* at its origin, and examined the resultant degenerations in the eye-muscles which it innervates and in their individual nerve-trunks.

In the nerve-trunks, extra-muscular and intra-muscular, the Wallerian degeneration clearly demonstrated that, with the exception of a few minute fibres, of variable number, derived perhaps from the ciliary ganglion, *all* myelinate nerve-fibres in all these eye-muscles degenerate. Therefore these eye-muscles derive the vast majority of their myelinate nerve-fibres from *n. oculomotorius*. The sensory innervation of these muscles is not, therefore, derivable from the fifth cranial pair. In accord with this, I found (α) that severance of both trigemini caused no obvious impairment of the movement of the eye-balls, (β) that the combined severance of both *nn. trigemini*, and of both optic nerves, even after section of the encephalic bulb, did not severely depress the tonus of the eye-muscles. Now we know that section of the sensory spinal roots belonging to muscles does very severely depress the tonus of them.

At the same time, I was struck with the long distance to which many of the nerve-fibres in these muscles travel forward towards the ocular tendons of the muscles. I was the more impressed with this fact because direct examination proved that the regions of the distribution of motor end-plates in these muscles is almost confined to the middle portion of the fleshy mass of the muscle. Further investigation of the course and destination of the nerve-fibres at the tendon end of the muscle revealed them (both in cat and monkey) undergoing terminal subdivision, and in numerous instances passing beyond into the bundles of the tendon itself. The terminations of some of these nerve-fibres lie within the tendons; many recurve again towards the muscular fibres, and end just at junction of muscle-fibre with tendon-bundle. The nerve-fibres in so terminating frequently become thick—as I have described in the case of muscle-spindles—with shortened internodes.

My observations have included also the fourth cranial pair, and with like result. Investigation of the sixth cranial pair is also in progress.

It also appears from the above that the absence of the distinct Kühne-Ruffini "spindles" from a muscle does not exclude the possession by it of sensorial end-organs, and of afferent nerve-fibres. This point is not without importance, because examination of various muscles has led me to the conclusion that the "spindle-organs" are absent from the following muscles:—From all the orbital eye-muscles; from the intrinsic muscles of the larynx, though Pacinian corpuscles occur, as in various other muscles; from the intrinsic muscles of the tongue, and from the diaphragm. It is notable that all these muscles belong to that set which are innervated by nerve-fibres of rather smaller calibre (Gaskell) than those supplying the skeletal muscles generally; that is to say, are innervated by the non-ganglionated splanchnic efferent nerves of Gaskell.

"On Boomerangs." By G. T. Walker, M.A., B.Sc., Fellow of Trinity College, Cambridge. Communicated by Prof. J. J. Thomson, F.R.S. Received March 15.

A typical returning boomerang resembles in general outline a symmetrical arc of a hyperbola, and is about 80 cm. in length measured along the curve. At the centre, where the dimensions of the cross section are greatest, the width is about 7 cm., and the thickness 1 cm.

Of the two faces, one is distinctly more rounded than the other; in addition the arms are twisted through about 4°, in the same manner as the blades of a right-handed screw propeller.

Such an implement, if thrown with its plane vertical, will describe a circular path of 40 or 50 metres in diameter, rising to a height of from 7 to 12 metres, and falling to the ground with its plane of rotation horizontal at a point somewhere near the thrower's feet.

The flight may be regarded as a case of steady motion, of which the circumstances gradually vary. In the more complicated, as well as the simpler, paths, observation makes it clear that everything depends on the changes in direction and inclination of the plane of the boomerang, and that the character of these changes is always the same; if they can be explained theoretically, the peculiarities of the motion may be accounted for.

Since the effects of the different forces at work are conflicting, it is necessary to adopt quantitative methods, even if the degree of accuracy attainable is not high; accordingly ratios

comparable with a tenth are treated as small, and their squares neglected.

If we regard the boomerang as a thin, slightly distorted lamina, and integrate over it the forces indicated in S. P. Langley's paper on "Experiments in Aerodynamics" ("Smithsonian Contributions to Knowledge," 1891), we can obtain equations of motion. From these, treating the motion as steady (to the first approximation), we may deduce the values of the angular velocities on which the direction of the axis of rotation depends. Five cases are worked out numerically, and the various effects of the "rounding" and "twisting" agree in character with the experimental facts; the discrepancies in actual magnitude are not larger than might, from the nature of the case, have been anticipated.

The theoretical results may be further tested by applying them to determine the conditions favourable to the production of other flights in which, after the first circle, a loop is described, either in front of or behind the thrower; in each of these cases success has been attained. An explanation is also afforded of the returning of a boomerang without "twist," made by Mr. O. Eckenstein, and of the wonderfully long, straight trajectories of some of the native non-returning implements.

Geological Society, April 28.—Dr. Henry Hicks, F.R.S., President, in the chair.—The President, referring to the exhibit of models of the dorsal and ventral aspect of *Triarthrus*, said that these had been prepared and sent to him by Mr. Charles E. Beecher, of Yale University Museum. He was sure that they would prove of great interest to the Fellows, who were well acquainted with the extremely careful work which Mr. Beecher had done in connection with *Triarthrus*.—The following communications were read:—Note on a portion of the Nubian Desert south-east of Korosko, by Captain H. G. Lyons, R.E., with notes on the petrology by Miss C. A. Raisin, and water-analyses by Miss E. Aston. A general description of the physical structure of the area, which consists mainly of Nubian sandstone and crystalline rocks, was given. Coming from Korosko to the Murrat Wells, the crystalline rocks are first met with on the east side of Jebel Raft. At Wadi dur Nabadi are ancient gold-workings. The crystalline rocks are both massive and schistose. On the crystalline mass of Jebel Raft, and apparently overlain by the Nubian sandstone, is a very coarse conglomerate containing fragments of crystalline rock, which appears to be older than the Nubian sandstone. The Nubian sandstone has little or no dip, and shows very slight variation in composition. The water-supply of the Nubian Desert is directly dependent on the rainfall, which is very irregular. The wells are sunk in the detritus of the valleys, and contain a large amount of mineral matter in solution, which renders them almost undrinkable; while the second source of supply—the rain-water reservoirs—are deep holes in the ravines which intersect the crystalline hills. These holes are attributed to water-action; and in the reservoir of Medina in Jebel Raft the spherical stones which assisted in forming the pothole still occur. The author believed that these ravines and reservoirs were formed at an earlier period than the present, when the rainfall was heavier. Miss Raisin gave accounts of both massive and schistose crystalline rocks, and also of sedimentary rocks. The crystalline rocks described include gneiss, hornblendite, gabbro, often much altered and resembling some of the Alpine gabbros, some allied rocks containing lustre-mottled hornblende, other forms of diabase, quartz-diorite, granite, felsites, certain schistose and a few distinctly fragmental rocks. None of the igneous rocks could be stated with certainty to have originated as a lava-flow. Many of them had undergone much alteration since their consolidation, and the results of this were described. There was clear evidence in many cases of erosion by desert-sand and the formation of a weathered coating. The schistose rocks did not present a very modern facies, and might be late Archæan or early Palæozoic. The massive crystallines may belong to different epochs, but include some rocks (such as the gneiss) resembling Archæan. These seemed to mark an eastward extension of the anticlinal axis previously traced by Captain Lyons to Wady Halfa in the Nile Valley from the west. Miss Aston gave two tables, one of which showed the actual amounts of substances found in the wells of Murrat, Bir Tilat Abda, and Bir Ab Anaga, while the second showed their approximate constitution.—On the origin of some of the gneisses of Anglesey, by Dr. Charles Callaway. The author still maintained the occurrence of two pre-Cambrian groups in Anglesey, the later of Pebidian age. In his paper a description was given of the production of gneissic structure in rocks of the earlier group occurring in the south of the island. The products of metamorphism were similar to those described by the author in the Malvern area. (1) Simple schists, granite is converted into mica-gneiss, diorite into hornblendic or chloritic gneiss, and felsite into mica-schist; (2) Injection-schists.

Zoological Society, May 4.—Mr. Herbert Druce, in the chair.—Mr. Oldfield Thomas exhibited a selection of the Mammals recently collected by Mr. A. Whyte during his expedition to the Nyika plateau and the Masuku mountains, North Nyasa. Mr. Thomas described as new a squirrel (*Xerus lucifer*), brilliant rufous throughout, with a black dorsal patch; a reed-rat (*Thryonomys sclateri*), allied to *T. gregorianus*, but with a longer tail, whitish instead of yellowish underside, and narrower and differently shaped skull; a mole-rat (*Georychus whytei*), like *G. nimrodi*, but with longer and broader frontal premaxillary processes; a pouched mouse (*Saccostomus elegans*), of a general buff colour and with a longer head than *S. campestris*; and *Mus nyikæ*, a rat of the size of *Mus chrysophilus*, but darker in colour and with a more rounded skull. A new subgeneric term (*Gerbilliscus*) was suggested for *Gerbillus boehmi*, Noack, of which Mr. Whyte had sent home specimens. Mr. Thomas also stated that the peculiar bulbous-tipped tail hairs described in *Petrodromus* proved to be confined to and characteristic of East African examples of the genus, which might therefore be specifically separated from the Zambezi forms as *P. sultani*.—Mr. Howard Saunders exhibited, on behalf of Mr. Henry Evans, a series of instantaneous photographs of the great grey seal (*Halichærus gryphus*) which had been taken in the Outer Hebrides.—Mr. J. E. S. Moore gave a general account, illustrated with the optical lantern, of the zoological results of his expedition to Lake Tanganyika in 1895 and 1896. Mr. Moore stated that the main object of the expedition had been to obtain materials for the morphological study of certain hitherto uninvestigated animal forms. It appeared that a key to the general interpretation of the lake-faunas of Central Africa would be most readily obtained by a study of their Molluscan Types. These showed that the faunas of most of the vast inland reservoirs of Africa were composed of normal lacustrine stocks, but that in Lake Tanganyika there were strange forms which certainly could not be included among such groups. All these forms appeared to have marine affinities; but, as they could not be directly associated with any living oceanic species, it was argued that they were probably the survivors of the marine fauna of some more ancient times, when Tanganyika was connected with the ocean. This theory was supported by the similarity of certain Tanganyika gastropods to ancient fossil shells.—A communication was read from Mr. Walter E. Collinge, on some European slugs of the genus *Arion*.—Mr. Sclater read a communication from Mr. Frederick J. Jackson, containing field-notes on the antelopes of Mau District, British East Africa.—The Rev. H. S. Gorham contributed a paper on the Coleoptera of the family *Endomychidæ* of the Eastern Hemisphere. Eighteen species were described, of which eleven were characterised as new.—Mr. F. E. Beddard, F.R.S., read a note upon the presence of intercentra in the vertebral column of birds. The existence of free intercentra in the caudal region was described in a number of genera belonging to many families of birds.

MANCHESTER.

Literary and Philosophical Society, April 27.—Dr. E. Schunck, F.R.S., President, in the chair.—Sir Henry E. Roscoe, F.R.S., was elected an honorary member. The following were elected officers and members of the Council for the ensuing year:—President, J. Cosmo Melvill; Vice-Presidents, Prof. O. Reynolds, F.R.S., Prof. A. Schuster, F.R.S., Charles Bailey, and W. H Johnson; Secretaries, R. F. Gwyther and Francis Jones; Treasurer, J. J. Ashworth; Librarian, W. E. Hoyle; other members of the Council, Prof. H. B. Dixon, F.R.S., Prof. H. Lamb, F.R.S., Dr. A. Hodgkinson, Francis Nicholson, J. E. King, and R. L. Taylor.—On the composition of some ancient Egyptian bronze and iron implements, by Dr. A. Harden. The author communicated the results of the analysis of two ancient iron chisels found in Thebes, and dating from about 600 B.C. Both of the implements contain a very small amount of carbon, and could not be rendered very hard by tempering. A specimen of bronze, dating from about 1500 B.C., was found to resemble modern bronze in its composition, consisting of copper alloyed with tin.

PARIS.

Academy of Sciences, May 3.—M. A. Chatin in the chair.—New classification of the Phanerogams, based upon the ovule and the seed, by M. Ph. van Tieghem. A summary of the preceding papers on this subject.—Researches on the composition of wheat, and on its analysis, by M. Aimé Gerard. During the process of milling, some 30 per cent. of the wheat is not included in the flour. The composition of this residue is given for samples of wheat of different origin, stress being laid upon the importance of suitable mechanical treatment preceding the chemical analysis.—The morphological signification of the caudal vertebræ, by M. Armand Sabatier.—Remarks by M. Faye on the presentation of the sixth volume of the "Annales de l'Observatoire de Nice."—Remarks by M. Darboux on the inauguration of the monument to M. Lobatschevsky at Kazan.—The Committees of Judges were appointed for the Grand Prize of the Physical Sciences, and for the Bordin, Damoiseau, Fourneyron, Pourat, and Gay Prizes.—On the law of variations of latitude, by M. F. Gonnessiat. Results of experiments undertaken with a view of seeing whether the meridian circle, at the same time that it furnished the absolute positions of the stars observed, could not also serve to show the variations of latitude with as much certainty as the differential methods hitherto adopted.—On the problem of Dirichlet, by M. S. Zaremba. An application to this problem of the notation of the theory of electricity.—On the comparative accuracy of the various methods used in securing the vertical in astronomical, geodesic, and topographical observations, by M. Ch. Lallemand. Four methods of levelling were compared—the use of a mercury bath as a plane mirror, the plumb-line, the spirit-level, and the contact of three points with a mercury bath, the last-named having been lately suggested as more rapid and more accurate. As a result of the experiments, supposing in each case the most favourable conditions, the spirit-level was found to be preferable, its accuracy being, in a portable apparatus, about fifteen times that of any of the other methods.—New properties of the kathode rays revealing their complex composition, by M. H. Deslandres. Whenever a kathode ray is deviated by a neighbouring body, it is, at the same time, divided into several distinct rays, which are unequally deviated.—On the partial polarisation of the radiations emitted by some luminous sources under the influence of the magnetic field, by MM. N. Egoroff and N. Georgiewsky. The polarisation in the case of most of the metals employed was shown exclusively in the rays most easily reversed. This was especially marked with copper. The rays from hydrogen and helium have, up to the present, given no definite results.—The part played by peroxides in the phenomena of slow oxidation, by M. A. Bach. In all the cases of slow oxidation by the air examined by the author, the application of reagents for hydrogen peroxide showed that this substance is invariably present. The results of experiments on the oxidising substance produced by the action of air upon palladium charged with hydrogen showed that in this case a higher oxidising power upon indigo than is possible for hydrogen peroxide, and it is suggested that a higher oxide, possibly H_2O_4, is present.—Study of the action of potassium permanganate upon cupric bromide, by MM. H. Baubigny and P. Rivals.—On the constitution of the metallic alloys, by M. Georges Charpy. From the study of a large number of alloys by the micrographical method conclusions are drawn concerning the nature of alloys in general. Eutectic alloys are stated to be not really homogeneous, but to consist of a mixture of the two constituent metals in the form of excessively thin laminæ, which are only visible under very high magnification.—Estimation of the dissolved oxygen in sea water, by MM. Albert Lévy and Félix Marboutin. The method previously adopted with success for ordinary potable water, namely, addition of ferrous oxide in known excess, and subsequent estimation of the excess with potassium permanganate solution, does not give good results in the presence of chlorides, and hence fails for sea water. The replacement of the permanganate by bichromate solution, however, removes this difficulty, the test analyses given being very concordant.—On the combinations of metallic salts with organic bases, by M. D. Tombeck. Aniline and pyridine bases are capable of forming definite combinations with the haloid salts of zinc and cadmium.—On a combination of silver chloride with methylamine, by M. R. Jarry. The compound formed is $AgCl(NH_2.CH_3)$. Its dissociation pressures are given for temperatures ranging from 0° to 65° C.—On the search for naphthol-yellow and analogous colouring matters in white wines and cordials, by MM. Alberto d'Aguiar and Wenceslau da Silva.—The evolutive cycle of the Coccidia in the Arthropods, by M. Louis Léger.—The origins of the vaso-dila or nerves and their trophic centres, by M. J. P. Morat.—On the parallel folds forming the mass of Mount Blanc, by M. J. Vallot.—On the Tectonic of the Nivollet-Revard Chain, by MM. J. Révil and J. Vivien.—On the determination of the proximate composition of the gluten in wheat flour, by M. E. Fleurent. The gluten is separated into two constituents, named respectively glutenine and gliadine, by treatment with a solution of alcoholic potash of suitable strength. The ratio of glutenine to gliadine determines the baking value of the flour.—Researches on the biological action of the X-rays, by MM. J. Sabrazes and P. Rivière.—The postulates of geometry, by M. Léon Fabre.—Influence of the temperature of fermentation upon the amount of nitrogen in wines, by MM. L. Roos and F. Chabert.

AMSTERDAM.

Royal Academy of Sciences, March 27.—Prof. van de Sande Bakhuyzen in the chair.—Mr. Verbeek, on the geology of Bangka and Billiton. Both islands consist of sedimentary rocks, probably of palæozoic age-sandstones, quartzites and shales, broken through by granites. Both of them are covered with quaternary sediments, loose sand and clay, the lowest (perhaps pliocene) strata of which contain tin ore; along the coast are alluvial deposits. The tin ore deposits are newer than the granite eruption, but probably they are not much more recent. Mr. Verbeek next dealt with "the glass-balls of Billiton." In the quaternary or, perhaps, pliocene tin ore deposits of Billiton there occur peculiar, rounded glass-balls with grooved surfaces; they are also found, though very rarely, in certain quaternary tuff strata in Java, and in the equally quaternary gold and platinum mines of south-eastern Borneo. The author classed these objects with the diluvial "Bouteille"-stones (Moldavites) of Bohemia, and the quaternary glass-balls found in Australia, and described by Stelzner (*Zeitschr. d. d. g. Gesellsch.*, 1893, p. 299). The origin of none of these bodies is known. They cannot be of volcanic origin, because the nearest volcanoes are too far distant, and have, moreover, produced glassy rocks of quite a different nature. For various reasons they cannot be artificial either. The author, therefore, took them to be of non-terrestrial origin, and considered it probable that they are thrown out by lunar volcanoes during the quaternary and, perhaps, already during the pliocene period. The author drew attention to the researches of Landerer (*Comptes rendus*, cix. p. 360, and cxi. p. 210), which, it seems, tend to show that a large portion of the surface of the moon consists of acid glass-rocks.—Prof. Hoffmann on the teleneurones in the retina of *Leuciscus rutilus*, in connection with researches by Mr. A. G. H. van Genderen Stort.—Prof. Haga presented, for publication in the *Proceedings*, a paper by Mr. J. W. Giltay, entitled "Polarisation of telephonic receivers." In 1884 the author proved that the speaking condenser required a charging battery to be employed, and that the telephone necessitated the use of a permanent magnet, because otherwise the apparatus renders the sounds to be reproduced an octave too high. The author has lately repeated the experiments with the better microphones of recent times, and found that some condensers (paraffin paper, gutta-percha paper) also speak intelligibly, though disagreeably, without a polarising battery being used, in consequence of the stronger telephonic charges penetrating into the insulator. A mica condenser, without a battery, is perfectly unintelligible. When it has been connected with the battery for a few seconds, it speaks very distinctly, and continues doing so for some seconds after the removal of the battery. When the battery is left in connection with the mica condenser for some time, the polarising action of the battery is found to decrease gradually. After a minute or two the sound has become quite unintelligible. As soon as the battery is removed, the sound immediately becomes very distinct, which, however, lasts only a few seconds. The author cannot yet give an explanation of this phenomenon. A not too tight coil of insulated wire without any iron gives perfectly the same results as a condenser with writing-paper: altogether unintelligible without the battery, quite distinct with it.—Prof. van der Waals gave, on behalf of Mr. Z. P. Bouman, for publication in the *Proceedings*, a survey of the results of an experimental inquiry into the emission and absorption of glass and quartz at different temperatures. The results obtained with the radio-micrometer (in a somewhat modified form) for plates 1 mm. in thickness may be formulated as

follows: The emission curve of glass reaches its maximum at $4.6\ \mu$, shifting but little with temperature. The curves have a broad "flattening" at about $3.5\ \mu - 4\ \mu$. The absorption curve shows the same particularity. The quotient $\frac{\text{emission}}{\text{absorption}}$ yields a curved line, whose maximum lies further towards the lesser λ's, absorption shifting in the inverse ratio to T. The emission and absorption of quartz correspond to each other. The two curves exhibit the same downward bends. In the quotient $\frac{\text{emission}}{\text{absorption}}$ the errors (per cent.) are too great to pronounce a positive opinion.

CONTENTS.

THURSDAY, MAY 20, 1897.

A PHILOSOPHICAL THEORY OF SELECTION.

Versuch einer philosophischen Selektionstheorie. Von Dr. Johannes Unbehaun aus Gotha. Pp. 150. (Jena: Gustav Fischer, 1896.)

THE object of this essay is to place the theory of selection on a purely deductive and abstract basis as distinguished from the concrete form in which it is made familiar to modern evolutionists through the writings of Darwin and Wallace. From the philosophical point of view, it is certainly desirable that we should realise that the particular kind of selection which is operative in species transformation, or in the production of artificial races, is only one phase of selection in the abstract, and any attempt to make our ideas on this subject more exact will be welcome to philosophical students of evolution. It is, in fact, somewhat remarkable that, while all working naturalists have now accepted the doctrine of evolution in one form or another, comparatively few have attempted to examine into the philosophical basis of the principles of selection. Dr. Unbehaun's discussion of the subject, if not exhaustive, is at any rate very suggestive, and as a contribution to a much neglected aspect of the philosophy of evolution the work may be safely recommended to English biologists.

The opening part of the essay, which treats of the principle of selection from the historical point of view, offers very little novelty. The author comes to the conclusion that the germ of the modern theory of selection is contained in the writings of the Greek philosophers. Empedocles appears to have had some hazy notions of the kind which did not produce much effect upon Aristotle, and the first definite utterance is attributed to Lucretius Carus the Epicurean. Those who take pleasure in reading into the poetic flights of ancient writers the discoveries of modern science, will derive interest from this section. There was a time in the history of science—especially in this country—when no new discovery was considered worthy of credence unless it could be shown to be in harmony with the views of the old philosophers. Those were the days when classical studies reigned supreme in our Universities, and when the would-be student of science was looked down upon as a poor creature. Happily for us the times have changed, and no worker in science is now seriously influenced by what the ancients thought. If he studies their writings, it is more from the point of view of academic interest than from a desire to find justification for his discoveries. The author of the present work does not appear to be acquainted with Prof. H. F. Osborn's most interesting discussion of the history of evolution in his book entitled "From the Greeks to Darwin."

As founders of the modern theory of selection, Dr. Unbehaun justly couples Darwin and Wallace. The distinction between evolution or descent with modification and selection is clearly grasped and emphasised by the former being called "Lamarckismus," and the latter "Darwinismus." Some pages are devoted to an exposition of the Darwinian principles, and the limited theory of selection elaborated by Malthus is also explained. There are not many points in this section with which we are not already familiar in this country, but the author certainly puts the case in a way calculated to clarify some of the current notions concerning the action of selection. Thus, with respect to the interpretation of the term "struggle for existence," it is pointed out that there are three possibilities, viz. struggle unaccompanied by actual extermination, and therefore of no effect as a selective process; struggle with extermination, as in ordinary natural selection; and extermination without struggle, which may or not produce selective action. The consideration of this last contingency brings out very clearly the difference between the struggle of competing organisms among themselves and the struggle with external (inorganic) conditions of environment. The outcome of this discussion is the conclusion that concurrent extermination of individuals or races is indispensable for the process of selection—in other words, that selection is concerned only with the existence or non-existence of individuals or assemblages of individuals, whether actual or potential.

After a brief exposition of the extension of the idea of selection from the organism as a whole, to the component parts (Wilhelm Roux, 1881), the author discusses palæontological selection, a subject which appears to be equivalent to a consideration of the conditions which favour the preservation of fossil remains, and for the complete understanding of which it is essential to study the conditions of preservation and destruction of animals and plants going on at the present time. In connection with this, there is brought forward a principle which is termed lithogenetic selection (Johannes Walther, 1895), and which may be paraphrased by saying that, although a geological formation may be laid down over a wide area of the surface of the earth, the local preservation of the rock material is determined by local conditions, organic and inorganic. The attempts which have been made to refer the processes of evolution in inorganic nature to the action of selection in any form, are considered by the author to have failed on account of the untenability of the fundamental assumptions. After a summing-up of the conditions essential for the formulation of a philosophical theory of selection, the author discusses, in an appendix, some further points of historical interest; viz. the claims of Herakleitos among the ancients, and of Kant and Wells among modern writers, to have entertained the idea of a struggle for existence. The utterances of the Greek philosopher are considered hazy; those of Kant and Wells are, as Haeckel has already shown (1889), more to the point.

The real work of building up "a purely deductive theory of selection on the most general foundation" begins in the second chapter, and selection is defined (p. 34) as the process by which, out of a number of objects which are in any way related to each other, some undergo extinction, while others survive within the same interval of time. A critical analysis of this conception leads to the conclusion that, instead of through selection, it is possible to approach the problem from the point of view of a system of objects (organisms) having different degrees of duration in time. Here, again, there may be selection with or without further development, according as the process is accompanied by renewal or not. In the latter case, a system may become modified in its average

characters through selection by the mere persistence or survival of residues. If the process of selection continues, the system will ultimately disappear altogether. In the case of selection with renewal the system does not undergo extinction, and, therefore, this is regarded as the more general case, since selection without renewal may be regarded as the limiting case in which the number of renewals is always equal to zero. The consideration of the mode of renewal by the origination of new objects within the system is followed by a mathematical discussion extending over several pages, and leading to a further elaboration of the idea of selection.

The idea of adaptation in the abstract is next discussed, and the conclusion arrived at is that between an object and its environment there may be three kinds of adaptation; viz. by a modification of the object itself to an unchangeable environment, by a modification of the environment by an unchangeable object, and by mutual adaptability when both are changeable. Following this, there is a discussion of certain special cases of the abstract theory of selection, and some very suggestive observations are made with respect to the difference between selection due to mere survival, and selection due to survival accompanied by actual picking out. The point is a fine one, but it appears to be philosophically sound; and the author introduces a term to express the latter, which might be conveniently translated into "progressive" (*fortschreitende*) selection. A mathematical appendix to Chapter ii. discusses the relations between the three magnitudes: (1) the number of objects present at a given period of time; (2) the number of renewals; and (3) the number of extinctions, on the assumption that the number of renewals is determined by the number of objects already present.

The concluding chapter deals with the limitations of the principle of selection and its consequences, and the introduction of the abstract results into concrete cases. Most instructive is the section in which the author points out the inapplicability of the principle of selection which governs the organic world to inorganic nature, such as the development of astronomical systems or to the formation of chemical compounds. The author deals very severely here with Carl du Prel, who appears to be responsible for an attempt to introduce the idea of the struggle for existence into the formation of the heavenly bodies. One of the main contentions of the present essay is, in fact, that while the organic world is entirely governed by the principle of progressive selection, the evolution of inorganic nature can be referred to no such principle.

The essay, of which a very brief account has now been given, will find a place in the literature of the philosophy of evolution. It deals with the question only on very broad grounds, and does not appeal, therefore, to special schools of evolutionists, or to special biological creeds beyond the school of pure selectionists. In this principle of selection the author sees a universal law of development for organic nature, which can be made the basis of a positive philosophy of evolution. He recognises the part played by Herbert Spencer, although reserving to himself the right of being sceptical with respect to Spencer's developmental machinery. Dr. Unbehaun's position is, perhaps, best defined as an attempt to recast the "Synthetic Philosophy" on purely Darwinian principles. It must be borne in mind that, in commending the work to the notice of English readers, we have not the scientific specialist in view. There is no new discovery of fact announced, and most of the principles are already familiar to English students of evolution. The essay is a contribution to philosophy rather than to science. It is the mode of treatment—the manner of presenting the case—that constitutes the chief value of the essay. The endeavour to formulate the principles of selection in exact terms capable of mathematical expression is being made from many sides, and, as a method of attacking such questions, has for some time found favour in this country. It is somewhat surprising, however, to find that no reference is made by the author to the work of Francis Galton and Prof. Karl Pearson, who have done more in this direction than any other writers.

R. MELDOLA.

ILLUSTRATED HISTOLOGY.

A Text-book of Histology: Descriptive and Practical. For the use of Students. By Arthur Clarkson, M.B., C.M.Edin. Pp. xx+554; with 174 original coloured illustrations. (Bristol: John Wright and Co. London: Simpkin, Marshall, Hamilton, Kent, and Co., Ltd., 1896.)

A BOOK which is illustrated in so lavish a manner as the one before us, is calculated to catch the eye; but it must also bear the test of critical examination. By its coloured representations of the tissues, it challenges comparison with the well-known "Atlas of Histology" of Klein and Noble Smith, which was published some seventeen years back. Except, however, that it is smaller and less costly, it suffers grievously by the comparison. Klein's "Atlas" contained accurate representations made from preparations which were thoroughly up to date, and their description included much that was at that time new; so that the whole work had an unmistakable air of originality, and has remained of permanent value. The book before us has pictures which are pretty, as far as gaudy colouring can make them so, but which are, many of them, sadly lacking in accuracy of detail, or have been made from preparations fixed by imperfect methods. The very first figures we come to in the book furnish an illustration of this statement. In the representation of the stages of karyokinesis, the monaster stage is shown with nine chromosomes, each splitting into two. In a succeeding figure of the same stage their number is reduced to eight, and in the following two figures, representing the stage of metakinesis of the nucleus, we find, respectively, eight and ten chromosomes instead of eighteen in each! Then, again, in such a simple figure as the representation of human blood-corpuscles a spherical white corpuscle is represented of, at least, twice the diameter of the red corpuscles; while in the drawing of newt's blood, amongst a number of distorted red corpuscles, and some impossible white cells and blood platelets, a non-nucleated fragment of a white corpuscle is inserted, as if it were a normal constituent! The author expresses his obligations to Prof. Rutherford for having taught him the art of constructing histological diagrams. We

wonder what Prof. Rutherford's feelings will be when he sees the diagram of two liver lobules, which is presented in Fig. 121.

Not that we, by any means, wish to imply that all or even most of the illustrations are of the character above specified. On the contrary, if we put aside accuracy of detail, many give a representation of ordinary microscopical objects which will rejoice the heart of the average student, because he will find that his preparations are "just like the drawings," *i.e.* as long as he sticks to the stereotyped methods which are customary in certain histological courses. And this is the key-note of the practical directions which are given in the text. A few common methods of general applicability, such as have been employed with occasional modifications for the last twenty years, are described, but many of the most valuable modern developments are conspicuous by their absence. We look in vain for the methylene-blue[1] method of Ehrlich for showing nerve-endings, the invaluable method for tracing degenerating nerves described by Marchi, the bulk-staining method of Heidenhain. The student is not taught how to examine each tissue in the fresh condition, but dependence is almost entirely placed upon sections and stained preparations. Formol is not even mentioned, although it has been for at least three years in constant use by histologists. These are faults of omission which cannot be excused by the statement in the preface that "only the well-known and well-tried methods are given." The above are all well-known and well-tried methods, and all students of histology ought to be familiar with them. Nor are faults of commission lacking. We are told that a tissue treated with nitrate of silver, and exposed to good daylight, requires for staining "a few hours to a day or two"; whereas every histologist knows that a few minutes under these circumstances is abundantly sufficient. The gustatory nerve-fibres are shown continued into the central ends of the gustatory cells. It is stated to be "not as yet very clearly decided as to whether the cylinder cells, the rod cells, or both, are to be regarded as the peripheral terminations of the olfactory nerve." The lens is described as "somewhat lozenge shaped"; and so on.

It is not a little remarkable that a work of this sort, lacking, as it does, the first principle of a text-book, accuracy, and compiled, as it acknowledgedly is, largely from other text-books, should have been the subject of numerous eulogistic notices in the medical, scientific, and even in the public press. One would hardly expect the *Scotsman* to think that the plates "represent what ought to be seen in perfect specimens," and the *Western Daily Press* to find that "the details are specified with a delicacy and microscopic accuracy which reveal innumerable anatomical beauties"; and it is somewhat surprising that another reviewer finds "the semi-diagrammatic representations of liver" (!), amongst others, "very helpful," and yet another hails the work as "an important contribution to histological literature." We can only regret that we have been unable to endorse these and many other expressions of opinion of an equally favourable character, which have been forwarded to us. For, in fact, the only part of the subject which bears any indication of having been specially studied by the author is that dealing with the ductless glands, especially the hæmal glands and the suprarenal capsules, and this shows a marked superiority of treatment. Had the whole book been written in the manner in which this part has been done, such eulogies might, perhaps, have been justifiable; but, as this is not the case, they entirely overshoot the mark, and can only lead to a feeling of disappointment on the part of the reader.

[1] The author is apparently unaware that methyl-blue and methylene-blue are two entirely different substances and have different histological uses, for he constantly uses the term methyl-blue where methylene-blue would be appropriate.

STUDIES ON EARLY MAN.

Studies in Ancient History. By J. F. M'Lennan. Second Series. Pp. xvi + 605. (London: Macmillan and Co., Ltd., 1896.)

IT is now many, many years since Mr. M'Lennan came before the public as an expounder of the beliefs and habits of early man, and we think that no one will deny to him the credit of having brought a trained mind and good powers of reasoning and deduction to his work. More than this, it must be admitted that he collected his facts with great care, and that although some of his results have not stood the test of time, they have at least served as finger-posts to point others to the right paths. More than twenty years have gone by since the first series of his "Studies in Ancient History" saw the light, and twenty years in the science of anthropology and its cognate subjects represent a vast amount of progress in these times. It was evident to Mr. M'Lennan himself that some of his views would have to be modified by the results of other workers, and though, alas, he never lived to re-edit a second edition of the "Studies," he was fortunate enough to have found a sympathetic supporter in his brother Mr. D. M'Lennan, who not only published as "a preliminary and polemical inquiry" "The Patriarchal Theory," but also a second edition of the "Studies" with notes by himself. Soon after this Mr. D. M'Lennan was himself carried off by death, and the late Prof. W. R. Smith undertook to finish the work which the two brothers had begun. About this time, however, Prof. W. R. Smith was deeply engaged in the study of Oriental kinship and marriage, and totemism, and he was also planning his series of lectures on "fundamental institutions"; it is evident that he had little leisure in which to arrange the labours of other workers. That little leisure, moreover, was broken in upon by the increase of the malady which subsequently caused his death, and as a matter of fact he left M'Lennan's work pretty well as he found it. Mrs. M'Lennan then determined to attempt the publication of all papers that were at all in a fit state, and she was fortunate enough to find not only a willing, but a most able friend in Mr. A. Platt, who as long as she lived assisted her in the work, and when she was dead, completed the labour of love which she had begun.

The second series of the "Studies" is divided into two parts; the first relates chiefly to kinship, totemism, marriage, the origin of exogamy, female infanticide, &c., and the second to the customs of the peoples of the Pacific Islands, America, Africa and Australia in these matters. Of the various chapters, only that on the

"Origin of Exogamy" has hitherto been printed. The reader will find during the course of his perusal of this volume that he is already familiar with a large number of the facts, and will be inclined to wonder why they are reproduced here without reference to the works in which they have already been printed; but it must be remembered that the works of W. R. Smith, Frazer and others have been published since the death of M'Lennan, and to add references of this kind was clearly outside the duties of the editors. Again, some of his views are given more fully, and others are disproved by an overwhelming mass of evidence in the splendid publications of the American Bureau of Ethnography which the Government of the United States have issued during the last fifteen years; but we cannot blame the editor for being silent on these points. M'Lennan began to work and to collect materials when the study of comparative ethnography was in its infancy, and he endeavoured to study everything for himself and at first hand. As other workers entered the field, and studied to specialise their knowledge, his task became greater and greater, until at length he was unable to cope with it; still in many respects his work is thorough, and even when his impressions and deductions from facts are wrong, they bear an honesty about them which is lacking in the work of more modern investigators. In a book dealing with so many peoples and countries it would be easy to pick holes and to raise an argument with tolerable frequency; and although we do not propose to do either the one or the other, still we must protest against the quotation on p. 520. Here it is gravely stated that the Zodiac was known in Egypt as early as B.C. 5800, but there is no evidence whatever extant on which to found such a decision; the home of the Zodiac was the country lying to the north-east of the Arabian Peninsula, and though it may have been known to both the Semitic and non-Semitic inhabitants of this region at such an early period, there is no proof that it was. Finally, we cannot help regretting that Mr. M'Lennan's "Studies" are without an index, for, in our opinion, one-half of their usefulness and value is lost thereby.

OUR BOOK SHELF.

Ferrets, their Management in Health and Disease; with Remarks on their Legal Status. By Nicholas Everitt. 12mo, pp. xv+209. Illustrated. (London: A. and C. Black, 1897.)

PROBABLY many of our readers who have not been brought up in the country would be shy of handling a ferret; but if they attend carefully to the directions given in this little volume, they may set aside their fears for the future. Admirable instructions are also given as to the management of these animals in health and in sickness, and likewise how to use them in the field; while a *résumé* of the legal status of ferrets will probably be useful to many. So far, indeed, as the breeding and management of these little mustelines are concerned, we may say, to use an expression of the author, that "what he does not know is not worth knowing."

Unfortunately, in common with many writers of works of a similar kind, the author has thought it necessary to give a preliminary chapter on the natural history of the ferret. Here he is in hopeless confusion. Although he describes the ferret as a species of *Mustela*, he says that it belongs to the genus *Putorius*; and further informs us that it is a natural species, whose native home is Africa. He also states that the beech, or stone marten, is a British species, and makes several remarkable assertions concerning other members of the group. The author may be reminded that there are writers on natural history since Buffon; and should the work reach a second edition, he would do well to engage the services of a competent naturalist to rewrite the first chapter. R. L.

Catalogue of the African Plants collected by Dr. F. Welwitsch in 1853-61. Part i. Dicotyledons. By W. P. Hiern. Pp. xxvi + 336. (London: Printed by order of the Trustees of the British Museum, 1896.)

DR. WELWITSCH, although an Austrian by birth, occupied the position of curator of the Lisbon Botanic Garden and Museum, when he was selected, in 1851, by the King of Portugal as naturalist to an expedition for exploring the Portuguese possessions on the West Coast of Africa. Between this date and 1861, he made very large collections, chiefly of plants. Although Dr. Welwitsch died in 1872, his collections have till recently remained unedited, partly owing to a dispute as to their ownership between his Trustees and the Portuguese Government, which ended in the Court of Chancery, partly owing to the difficulty in finding a compiler and editor. This office was finally placed, by the Trustees of the British Museum, as far as the flowering plants are concerned, in the very competent hands of Mr. W. P. Hiern, who has now brought out the first part, comprising the natural orders of Dicotyledons from Ranunculaceæ to Rhizophoraceæ. The work has been one of great labour, a large number of new species and some new genera being described; and we may congratulate the systematic botanist on so important an addition to our knowledge of the flora of Tropical Africa.

A. W. B.

Pioneers of Evolution from Thales to Huxley; with an Intermediate Chapter on the Causes of Arrest of the Movement. By Edward Clodd. Pp. x + 250. (London: Grant Richards, 1897.)

MR. CLODD has produced an interesting book, in which is told "the story of the origin of the Evolution idea in Ionia, and, after long arrest, of the revival of that idea in modern times, when its profound and permanent influence on thought in all directions, and, therefore, on human relations and conduct, is apparent." The volume is divided into four parts, which deal successively with the Pioneers of Evolution from Thales to Lucretius, the Arrest of Inquiry, the Renascence of Science, and Modern Evolution. It should be read by the great body of science students in our University Colleges and technical schools, who, too often, in following special branches of science, lose sight of the great generalisations which have, during the latter part of this century, so completely altered the complexion and tendency of ideas on every subject of thought.

The author sketches the chief results which have come from the recognition of the principles of evolution, not only in biological provinces, but in all departments of human knowledge; and he has, in so doing, produced an attractive and wonderfully clear little volume.

It may be worth while to point out that the statement that nebulæ are "masses of glowing hydrogen and nitrogen gases" (p. 164) needs correction; for nitrogen, as a nebular constituent, is now relegated to the limbo of departed ideas. Mr. Clodd should have verified his statement by himself taking the advice which he offers Lord Salisbury on p. 165. The reference to "the complex jelly-like *protoplasm*, or, as some call it, *nuclein* or *nucleoplasm*" (p. 103), also needs to be made accurate, for in its present form it will give readers the idea that the three words we have italicised are synonymous. The book contains good portraits of Darwin, Russel Wallace, Herbert Spencer, and Huxley.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Immunity from Mosquito Bites.

WITH the mosquito as he is, and as he has been for forty-six years. in the territory on both sides of the Mississippi River from Memphis, Tenn., to New Orleans, and along the Gulf of Mexico for five hundred miles, in the cypress swamps, palmetto and cane-brakes, on the lower river lands, winter and summer, following my business of telegraphy, I am intimately acquainted; and from this long and varied experience can say definitely for myself that I have no immunity from their attacks. Every bite yesterday, or forty-six years ago, produced a wound, generally a white, callous swelling from one quarter to three-quarters of an inch in diameter, and as high as a quarter of an inch, which remains forty-five to sixty minutes, with more or less pain in all, and fever in many cases. And this whether it was the bite of the fierce gallinipper of the swamps, which stings through a flannel shirt, or the little zebra-legged thing—the shyest, slyest, meanest and most venomous of them all—which invades the heart of the city, away from the foliage, the common haunts of the other varieties.

While I have to be vigilant in warding them off, my children sitting around are comparatively undisturbed, and other people suffer nothing from them; so it seems the mosquito has the power of selection.

But if I have experienced no immunity from mosquito poison, I have enjoyed it other ways, which it may be interesting to state. When I qualified as an operator in Mississippi, I was given a station to which was attached fifty miles of wire, which I was to keep in order, repair breaks, remove leaks, and replace insulators. The line was mostly on trees, few poles being used, and the foliage, including vines, had to be kept down. The latter were especially dangerous and of rapid growth, and among them was the *Rhus toxicodendron*, but I knew nothing of its qualities; and when I came across it, which I did at the very outset, I cut it at the roots, and taking hold of it with naked hands, pulled it off the trees and poles without ever experiencing the least effects from it. Others are poisoned by its touch, and are laid up for weeks and months, their sufferings being produced by periodical eruptions appearing annually on the hands, face or neck for many years. DAVID FLANERY.

Memphis, Tenn., U.S.A., April 28.

Identical Customs of Dyaks and of Races around Assam.

THE deplorably backward state of anthropology in England and India is effectually exposed by the recent publication of Mr. Ling Roth's "Natives of Sarawak and British North Borneo." Beautifully illustrated, exhaustive in treatment, too expensive to be procurable among working students, and exasperatingly unweildy, it is a monument of shame to us, as a race; the more so when we see that only 700 copies are to be issued, "no cheaper edition" *guaranteed!* and the beautiful plates to be destroyed!

As a record of our apathy and ignorance it could hardly be surpassed. Here is a really wonderful work, lavishly got up, two huge volumes full of the most valuable matter, quoted from the best authorities, unlimited speculation as to where these races came from, and as to how some of their singular customs arose, such as "head-hunting," &c., and, as far as I can see, not the faintest suspicion that these customs came, with the race itself, from Assam.

The late Captain Otto E. Ehlers, with whom I spent ten days here in the early part of 1895, was so impressed with the fact, at last, that these Abor-Noga savages around Assam are the race stock whence the Batta-Dyak developed, that he determined to first examine and collect among our groups, and later on visit Borneo. With this object in view we visited together some of the eastern Nogas. He then went among the little-known "Apa Tanangs," and later on the "Nogas" along the south border, "A-nga-mi" and others, making huge collections. Unfortunately he contracted fever, and was ordered off for a long sea voyage, intending to visit Papua so as to collate the races there, closely allied to our Kol; and had intended taking Borneo on the return voyage. His untimely death in Papua put an end to it all, and what has become of his notes and collections I do not know. This, however, I can vouch for, *i.e.* that he was thoroughly convinced that in and round Assam we have a huge mine of anthropological lore, of which our men of science have not the faintest suspicion, and to which fact I have now for some years in vain endeavoured to draw attention.

In reading Mr. Ling Roth's work, it becomes at last almost wearisome to note the identity of the Bornean customs with those of our semi-savage races, down even to trivial details, the only marked differences being those due to developments through contact with more advanced races *later on*, such as the early and pre-Musalman, and Brahmanical influences, *viâ* Java. One of the greatest stumbling-blocks in collating our races with those of the Archipelago is the persistence with which languages are looked upon as the main tests of racial affinity. Occasionally language is invaluable, but at other times, as in this case, it stands a bad second, or even third, both custom and physique being more reliable. We often have curious proofs of this even here, on a small area. For instance, I am now endeavouring to get a collection of the peculiar armless fringed jackets worn by the men among E. Nogas, Mishmi, Miri, Apatanang, Mikir, Kasia, Garo, Kuki, &c. I have seen these being woven by Noga women, the loom simply two sticks in the ground, with a cross-piece (Fig. 1, A), to which the narrow web is attached; another stick, B, at about six feet distant from A, and over which the threads pass, is held tightly by a strap and strings which pass round the weaver's back, as she sits on the ground.

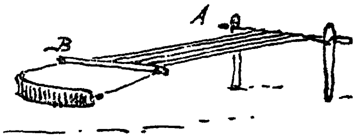

FIG. 1.

The small piece of cloth when finished, with patterns often woven in of coloured cotton or goat's hair, is some 4 feet long by 8 inches or 10 inches wide. The ends of threads form a fringe, thus (Fig. 2):—

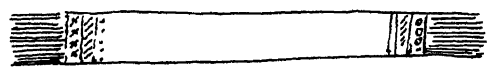

FIG. 2.

Now, two of these pieces are sewn together, so as to leave a hole in the centre (Fig. 3);

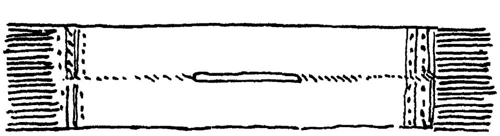

FIG. 3.

and then, after turning over, are sewn down the sides, so as to leave arm-holes (Fig. 4).

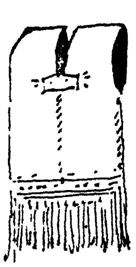

FIG. 4.

The whole thing is too methodical, and identical, to be an accidental resemblance—all are practically alike in details of construction; yet we not only find this jacket among all these tribes, but among the Dyaks, a proof (among many others) that, as a racial relic, it is *older than the languages* of these races around Assam.

But the lists of identical customs, seen between these races here, and those in Borneo, from "head-hunting," and its causes, building on piles, tatooing, &c., down to such trivial details as the value attached to the hornbill's feathers, curious fences, is interminable, quite impossible to put in a letter.

What I desire to point out is the need for systematic research among these races around Assam and in the ultra-Indian peninsula; they are practically unknown to anthropologists, and unless soon taken in hand, a vast amount of most valuable history will

be lost for ever. Some of the most valuable racial curios are now actually unprocurable. The long straight swords of the Mishmi, in the extreme east, were formerly found among all the races north of the valley as far west as the Kuki, and are now a tradition only. The Noga "Kyep," hide cuirass, identical with that of the Niasi, west of Sumatra, are impossible to get hold of, though common here thirty years ago—firearms rendering them useless.

An organised army of intelligent workers is badly wanted to save the stores of unwritten history seen in *customs* among all these races. They are pre-Aryan races, and if but a tenth of the time and money now being lavished on the Aryan remains, here and at home, were devoted to these far older, and far more interesting races, the result would astonish home folk. The races of the Pacific, and Archipelago (Australia included), came from India, as Polynesian investigators well know, but cannot easily join the proofs across the Malayan region.

Can nothing be done to arouse attention to this matter? Some of the customs are of the greatest possible value in the elucidation of the development of early human institutions such as marriage; and in the *Journal* of the Asiatic Society of Bengal, vol. lxi. pt. ii., No. 3, 1892, pp. 246 to 269, I drew attention to one of them in "The communal barracks of primitive races," a vast subject, on which alone there is enough to occupy many experts for several years, as its ramifications extend from West Africa to Eastern Polynesia, and from the Himalaya to New Zealand.

There are many willing and capable workers in the East, but scattered over a vast area; a central "association" is needed, say at Singapore, to and from which communication is easy. An association of scattered students, rather than a new society, is wanted, and it would cost very little if the local branch of the Asiatic Society took the matter in hand as a branch of its work, charging those engaged in research a transmission fee on all that passes.

At the present moment I am most anxious to get in touch with some one in Formosa, so as to procure photos of the savages, their houses, &c., to compare with our Noga, who, I believe, are the same race stock, but I am not able to get the names and addresses of workers there; a central association at Singapore could very probably afford help in such matters.

The Anthropological Institute of Great Britain and Ireland is too far off to give this aid; besides, it is not a live society, or anthropology would not be in such a pitiable slough as we see it here. The collection of life-sized nude nondescript effigies in the Indian Museum reveals our state at a glance; they are to amuse the hundreds of natives who gape at them daily. The value of it as a collection is measured by the *numbers* who stare and get thoroughly mystified, and this is proudly published every week. As an ethnological collection it is enough to drive an expert mad. S. E. PEAL.

Sibsagar, March 31.

A Curious Luminous Phenomenon.

THE phenomenon mentioned on p. 31 of NATURE (May 13), is undoubtedly subjective, and has to do with the fatigue of the retina.

I observed it very markedly in the case of an orange round which I was skating on the open-air ice-rinks in the Engadine; all the country about being white, and the ice, too, being dazzling.

The blue-violet margin to the orange was zero, or at a minimum, when I fixed my eye on a point on the orange. It was at a maximum when I glanced quickly round the orange, or when the orange rolled. In the latter case it was unsymmetrical and "trailed."

I satisfied myself, by the experiments that I tried, that the portion of the retina protected from the white glare by the image of the orange, received an impression of blue-violet light when the protection of this image was removed owing to the movement of the eye or of the object; but that this peculiar condition of the portion of the retina in question was very transitory.

It is possible that temperature affects the phenomenon indirectly; since the eye may be more unsteady, and wander more, when the temperature is low.

Experimenting in England with less white and dazzling ice and landscape I found the phenomenon less marked. It was very brilliant and beautiful in the Engadine.

I feel sure that if any observer notices the effect of keeping his eye fixed on some point of the body so as to keep the image on a constant portion of the retina, he will come to the same conclusion as myself. W. LARDEN.

R.N.E. College, Devonport.

Röntgen Rays.

I HAVE had a focus-tube constructed, in which the distance between the electrodes can be varied, after Mr. Campbell Swinton's pattern, but in which the kathode is made the movable electrode, and the adjustment is made by magnetic control. This is effected by attaching a disc of soft iron to the sliding-rod of the kathode. The advantage of this arrangement is that the kathode can be moved up to, or away from, the anode while the tube is working, so that the best effect can be at once obtained. The resistance is, as Mr. Swinton has pointed out, greater when the electrodes are close together than when they are far apart. The best fluorescent effects are, however, obtained when the electrodes are so close together (about one millimetre apart) that a very bright arcing discharge occurs between them. The screen is now lighted up much more brilliantly than when they are at any other distance apart. The very bright fluorescence is only obtained when the arcing discharge occurs. If the electrodes are brought any nearer together, the platinum anode becomes red-hot, the fluorescence fails, and the resistance of the tube increases very rapidly. I do not remember having seen this noted before.

Edinburgh, May 10. DAWSON TURNER.

THE ROYAL SOCIETY SELECTED CANDIDATES.

THE following are the names and qualifications of the fifteen candidates selected by the Council of the Royal Society, to be recommended for election into the Society this year:—

ROBERT BELL,

M.D., B.A.Sc., LL.D. Assistant Director of the Geological Survey of Canada. Has been actively engaged in the field work of the Survey for thirty-six years. Was concurrently Professor of Chemistry and Geology, Queen's University, Kingston, for five sessions, 1863–68; Naturalist and Medical Officer on the Government Expeditions to Hudson Bay, 1884–85; Royal Commissioner on the Mineral Resources of Ontario, 1888. Distinguished for his services to Canadian Geology, having worked over large sections of the Dominion east of the Rocky Mountains. Has made extensive researches among the Laurentian and Huronian Rocks, and in reference to Glacial phenomena. Has added materially to our knowledge of Zoology and Botany—more especially of the Forestry—of Canada. Has published nearly 100 reports and papers of a scientific character. They include upwards of twenty reports, some accompanied by maps of the Geological Survey, between 1857 and 1890, giving the results of geological and topographical surveys and explorations on both sides of Hudson Bay and Straits, along the principal waters between the upper Great Lakes and James Bay, and of those between the Winnipeg Basin and Hudson Bay, the first survey of Lake Nipigon, geological surveys of the Canadian Sudbury Mining Districts, the Gaspé District, the Lake Peninsula of Ontario, and in other parts of the extensive regions of Canada. Although much condensed, these Reports cover about 930 pp. royal 8vo. Among many additional publications may be mentioned "The Causes of the Fertility of the Land in the Canadian N.W. Territories," "The Petroleum Field of Ontario," "The Huronian System in Canada," "Glacial Phenomena in Canada," "The Geology of Ontario, with special reference to Economic Minerals," "The Laurentian and Huronian Systems North of Lake Huron," "The Origin of Gneiss," "The Forests of Canada," "The Forest Fires in Northern Canada."

Supplementary Certificate.—Since the date of the above certificate Mr. Bell has made further geological investigations of importance north of Lake Huron, and a survey of a large river previously unknown to geography in the country south-east of James Bay, besides a general geological and topographical exploration of an extensive area in that region. He has now been connected with the Geological Survey of Canada for forty years,

and has published 135 scientific papers, reports, &c., besides abstracts of 42 others read by the author. The titles of most of these are published in the *Transactions of the Royal Society of Canada for* 1894.

SIR WILLIAM HENRY BROADBENT,

F.R.C.P. Physician in Ordinary to H.R.H. the Prince of Wales. Consulting Physician to St. Mary's Hospital, and to the London Fever Hospital. Late Lecturer on Medicine, St. Mary's Hospital. Late Senior-Censor of the Royal College of Physicians. Late President of the Harveian, Clinical, and Neurological Societies. Late Examiner in Medicine, University of Cambridge, University of London, and at the Royal College of Physicians of London. Is very eminently distinguished as a physician, and is the author of numerous important Memoirs bearing upon the Physiology and Pathology of the Nervous System and the Heart; and also upon scientific principles of Therapeutics. The following are some of his principal contributions:—"The Sensory Motor Ganglia and Association of Nerve Nuclei" (*Brit. and For. Med. Chir. Rev.*, 1866); "On the Structure of the Cerebral Hemispheres" (*Proc. Roy. Soc.*, 1869); "On the Cerebral Mechanism of Speech and Thought" (*Trans. Med. Chir. Soc.*, 1872); "An Attempt to apply Chemical Principles in Explanation of the Action of Remedies and Poisons" (London, 1869); a work "On the Pulse" (London, 1890); Lettsomian Lectures, before the Medical Society, on "Syphilitic Diseases of the Nervous System," 1874; Harveian Lectures, before the Harveian Society, on "Prognosis in Valvular Disease of the Heart," 1884; Croonian Lectures, before the Royal College of Physicians, on "The Pulse," 1887; Lumleian Lectures, before the Royal College of Physicians, on "Structural Diseases of the Heart," 1891. Numerous other papers have been published in the Medical Journals and Transactions of the Medical Societies.

CHARLES CHREE,

D.Sc., M.A. (Cantab.). Superintendent of the Kew Observatory. Author of the following Memoirs, and many others on analogous subjects:—(1) "Effects of Pressure on the Magnetisation of Cobalt" (*Phil. Trans.*, 1890); (2) "Stresses and Strains in Isotropic Elastic Solid Ellipsoids," &c. (*Proc. Roy. Soc.*, 1895); (3) "Conduction of Heat in Liquids" (*ibid.*, 1887); (4) "A Solution of the Equations for Equilibrium of Elastic Solids," &c. (*Camb. Phil. Trans.*, vol. xv.); (5) "On some Compound Vibrating Systems" (*ibid.*, vol. xv.); (6) "Changes in Dimensions of Solids due to given Systems of Forces" (*ibid.*, vol. xv.); (7) "The Isotropic Elastic Sphere and Spherical Shell" (*Camb. Phil. Trans.*, vol. xv.); (8) "Forced Vibrations in Isotropic Elastic Solid Spheres and Spherical Shells" (*ibid.*, vol. xvi.); (9) "Rotating Elastic Solid Cylinders of Elliptic Section" (*Phil. Mag.*, 1892); (10) "Contributions to the Theory of the Robinson Cup Anemometer" (*Phil. Mag.*, 1895); (11) "Longitudinal Vibrations of Acolotropic Bars with One Axis of Material Symmetry" (*Quart. Journ. Math.*, 1890); (12) "Isotropic Elastic Solids of nearly Spherical Form" (*Amer. Journ. Math.*, vol. xvi.).

HENRY JOHN ELWES,

F.L.S., F.Z.S. President of the Entomological Society (1893–94). Vice-President of the Horticultural Society (1878-80). Late Captain, Scots Fusilier Guards. Has for many years devoted himself to the study of Ornithology and Entomology, and has travelled extensively with the view of investigating the migrations, variations, and geographical distribution of birds and certain classes of insects over large areas of the northern hemisphere. In pursuance of his researches he has visited India on four occasions (1870, 1876, 1880, 1886), extending his observations from Travancore to the Punjab, Assam and the loftiest Himalaya bordering on Tibet; the Eastern and Western United States, Canada, and Mexico (1888, 1893); Greece, Turkey, Asia Minor, and the Crimea (1869, 1874); Algeria (1882); and all parts of Europe. His collections and observations have yielded very important results, notably his paper "On the Geographical Distribution of Asiatic Birds" (*Proc. Zool. Soc.*, 1873), wherein the Himalayan and Chinese Avi-faunas are shown to be one. Other papers are: "On the Ornithology of the Cardamum Hills, Travancore" (*Ibis*, 1870); "On the Genus *Parnassius*" (*Proc. Zool. Soc.*, 1886); "On *Hemicurus*" (*Ibis*, 1872); "On the Papilionidæ of the Eastern Alps" (*Entom. Monthly Mag.*, 1880); and of "The Sikkim Himalaya" (*Proc. Zool. Soc.*, 1882); and of "Amur-land, N. China and Japan" (*loc. cit.*, 1881); and of the "Naga and Karen Hills" (*loc. cit.*, 1891–92). Mr. Elwes is author of a valuable memoir on the genus *Lilium*, and has, during his travels, communicated many interesting plants to the Royal Gardens, Kew.

JOHN SCOTT HALDANE,

M.D., M.A., M.R.C.P. (Edin.). Hon. M.A., Oxford. Lecturer in Physiology, University of Oxford. Author of the following and of other Memoirs:—"The Elimination of Aromatic Bodies in Fever" (*Journ. Physiol.*, vol. ix., 1888); "The Carbonic Acid, Organic Matter, and Micro-organisms in Air" (with Prof. Carnelley and Dr. Anderson), (*Phil. Trans.*, 1887); "The Air of Sewers" (with Prof. Carnelley), (*Proc. Roy. Soc.*, 1887); "The Air of Buildings and Sewers" (*Trans. Sanit. Inst.*, 1887); "The Accurate Determination of the Carbonic Acid and Moisture in Air" (with Mr. Pembrey), (*Phil. Mag.*, 1890); "A New Form of Apparatus for Measuring the Respiratory Exchange" (*Journ. Physiol.*, vol. xix., 1892); "The Physiological Effects of Air vitiated by Respiration" (with Mr. Lorrain Smith), (*Journ. of Pathol. and Bacteriol.*, 1892); "The Toxic Action of Expired Air" (with Mr. Smith), (*ibid.*, 1893); "An Improved Form of Animal Calorimeter" (with Drs. Hale White and Washbourn), (*Journ. Physiol.*, vol. xvi., 1894); "On Red Blood Corpuscles of Different Specific Oxygen Capacities" (with Mr. Smith), (*ibid.*, vol. xvi., 1894); "The Nature and Physiological Action of Black Damp" (*Proc. Roy. Soc.*, vol. lvii.); "Investigations on Composition, Occurrence, and Properties of Black Damp" (with Mr. W. N. Atkinson), (*Trans. Fed. Inst. Mining Eng.*, 1895); "The Relation of Carbonic Oxide to Oxygen Tension" (*Journ. Physiol.*, vol. xviii., 1889).

Supplementary Certificate.—Report to the Home Secretary on the Causes of Death in Colliery Explosions, 1896 (Parliamentary Paper); "The Nature and Sources of the Suffocation Gas met with in Wells" (*Trans. Fed. Inst. Mining Engineers*, vol. xi., p. 265); "Oxygen Fusion of Arterial Blood" (with Prof. Lorrain Smith), (*Journ. Physiol.*, in the Press).

WILLIAM A. HASWELL,

M.A., D.Sc. (Edin.). F.L.S. Vice-President Linnean Society of New South Wales. Trustee of the Australian Museum. Corr. Memb. Royal Society of Tasmania. Memb. K. Leopold.-Carol. Deutsche Akad., Halle. Challis Professor of Zoology, University of Sydney, N.S.W. Distinguished as a zoologist and comparative anatomist. Author of seventy-four papers, mainly morphological, including the following:—"Catalogue of the Australian Stalk and Sessile-eyed Crustacea," 1882; "On *Temnocephala*, an aberrant Monogenetic Trematode" (*Quart. Journ. Micros. Sci.*, 1888); "A Monograph of Temnocephaleæ" (Macleay Memorial Volume, 1892); "A Monograph of the Australian Aphroditeæ" (*Proc. Linn. Soc. N.S.W.*, 1882); "The Marine Annelides of the Order Serpulea" (*ibid.*, 1884); "On the Structure of the so-called Glandular Ventricle of Syllis" (*Quart. Journ. Micros. Sci.*, 1886); "On an apparently New Type of *Platyhelminthis*" (Macleay Memorial Volume, 1892); "A Revision of the Australian *Læmodipoda*" (*Proc. Linn. Soc. N.S.W.*, 1884); "A Revision of the Australian Isopoda" (*ibid.*); "Studies on the Elasmobranch Skeleton" (*ibid.*); "On the Structure of the Paired Fins of Ceratodus, &c." (*ibid.*, 1882); "Observations on the Early Stages in the Development of the Emu" (*ibid.*, 1887); "On Polycercus, a Proliferating Cistode Parasite of the Earthworms" (*ibid.*, 1893); "A Comparative Study of Striated Muscle" (*Quart. Journ. Micros. Sci.*, vol. xxx.), in conjunction with Mr. J. P. Hill.

GEORGE BOND HOWES,

F.L.S., F.Z.S., Assistant Professor of Zoology in the Royal College of Science, London. Member of Council of the Linnean Society, and of the Anatomical Society. Examiner in Zoology, Victoria University, and for the University of New Zealand. Author of an "Atlas of Elementary Biology," and joint co-author of the revised and extended edition of "Huxley and Martin's Practical Biology." Author of numerous papers on Morphology, dealing especially with the Ichthyopsida and Mammalia, of which the following are the more important:—"On some points in the Anatomy of the Porpoise" (*Journ. Anat. and Phys.*, vol. xiv. p. 467); "Notes on the Cranio-Facial

Skeleton of the Sturgeon" (incorporated in Prof. W. K. Parker's monograph in *Phil. Trans.*, 1882, p. 171); "The Morphology of the Mammalian Coracoid" (*Journ. Anat. and Phys.*, vol. xxi. p. 190); "On the Skeleton and Affinities of the Paired Fins of Ceratodus and those of the Elasmobranchii" (*Proc. Zool. Soc.*, 1887, p. 3); "On a hitherto Unrecognised Feature in the Larynx of the Anourous Amphibia" (*ibid.*, p. 491); "Rabbit with an Intra-Narial Epiglottis, with a suggestion concerning the Phylogeny of the Mammalian Respiratory Apparatus" (*Journ. Anat. and Phys.*, vol. xxiii. p. 263); "Additional Observations upon Intra-Narial Epiglottis" (*ibid.*, p. 587); "Variation in the Kidney of *Raia clavata*; its Nature, Range, and probable Significance" (*ibid.*, vol. xxiv. p. 407); "On the Visceral Anatomy of the Australia Torpedo" (*ibid.*, p. 669); "Observations on the Pectoral Fin-Skeleton of Living Batoid Fishes, and of the Extinct Genus Squaloraja," &c. (*ibid.*, p. 675); "On some Hermaphrodite Genitalia in *Gadus Morrhua*," &c. (*Journ. Linn. Soc. Zoology*, vol. xxiii. p. 539); "On the Probable Existence of a Jacobson's Organ among the Crocodilia; with Observations upon the Skeleton of that organ in the Mammalia," &c. (*Proc. Zool. Soc.*, 1891, p. 148); "Notes on the Shoulder-Girdle of certain Dicynodont Reptiles" (*ibid.*, vol. xxvi. p. 403); "On the Affinities, Intra-relationships, and Systematic Position of the Marsipobranchiata" *Trans. Liverpool Biol. Soc.*, vol. vi. p. 122), &c.

Supplementary Certificate.—Professor of Zoology, Royal College of Science, Treasurer Anatomical Society of Great Britain, and President of the Malacological Society of London; Zoological Secretary of the Linnean Society; Memb. Council Zoological Society. Has continued work on "The Morphology of Coracoid of Terrestrial Vertebrata" (*Proc. Zool. Soc.*, 1893, p. 385), and published papers dealing, among other subjects, with:—"Morphology of Pelvic Girdle of Mammalia" (*Journ. Anat. Phys.*, vol. xxvii. p. 543); "Variation and Development of the Vertebral and Limb-Skeleton of Amphibia" (*Proc. Zool. Soc.*, 1893, p. 268); Synostosis and Curvature of the Spine in Fishes" (*ibid.*, 1894, p. 95); "Types of Modification of Mammalian Hyoid" (*Journ. Anat. Phys*, vol. xxx. p. 513). Has edited and annotated English translation of Wiedersheim's "Bau des Menschen."

F. STANLEY KIPPING,

D.Sc. (Lond.), Ph.D. (Munich). Lecturer and Chief Assistant in the Chemical Department of the City and Guilds of London Institute, Central Technical College. Distinguished as an original and very skilful and persistent worker in Chemistry. Author of sixteen papers published in the *Transactions of the Chemical Society*, and of others in the *Journal of the German Chemical Society*, the following being the titles of several of these:—"The Synthetical Formation of Closed Carbon Chains in the Aromatic Series"; "Action of Phosphoric Anhydride on Fatty Acids" (3 parts); "Hydrindone and its Derivatives"; "Formation of the Hydrocarbon Truxene"; (in conjunction with Dr. Perkin) "Diacetylpentane and Dibenzoylpentane"; "Derivatives of Phenylhexamethylene"; "Synthesis of Dimethyldihydroxy hepamethylene," &c.; (in conjunction with Dr. Armstrong) "The Formation of Ketones from Camphor"; (in conjunction with Mr. Pope) "Sulphonic Derivatives of Camphor."

GEORGE BALLARD MATHEWS,

M.A., Professor of Mathematics in the University College of North Wales. Late Fellow of St. John's College, Cambridge; Fellow of University College, London. Eminent Mathematician. Author of the following works of merit in connection with Mathematics:—"Theory of Numbers" (1892); "Complex Multiplication Moduli of Elliptic Functions for the Determinants −53 and −61" (*Proc. Lond. Math. Soc.*, vol. xxi.); "On Class Invariants" (*ibid.*, vol. xxi.); "Note on Dirichlet's Formula for the Number of Classes of Binary Quadratic Forms for a Complex Determinant" (*ibid*, vol. xxiii.); "On Binary Quadratic Forms with Complex Coefficients" (*Quart. Journ. Math.*, vol. xxv.); "On the Classification of Symmetric Functions" (*ibid.*); "On the Expansion of the Coordinates of a Point upon a Tortuous Curve in terms of the Arc" (*ibid.*, vol. xxvi.); "Irregular Determinants and Sub-triplicate Forms" (*Mess. Math.*, vol. xx.); and others, a list of which is sent.

GEORGE ROBERT MILNE MURRAY,

F.L.S., F.R.S.E. Assistant (First Class), Department of Botany, British Museum. Naturalist to the Solar Eclipse Expedition to Grenada, 1886. Examiner in Botany, Glasgow University, 1887-92; Victoria University, 1889-92. Lecturer on Botany at the Royal Veterinary College, London. Author of numerous papers on the structure, classification, and distribution of Cryptogams, of which the following are the more important:—"Investigations into the Infection of Fishes with *Saprolegnia ferax*" (*Reports of the Inspector of Fisheries*, 1883-85); "On the Outer Peridium of *Broomeia*" (*Journ Linn. Soc.*, 1882); "On two New Species of *Lentinus*, one of them growing on a large Sclerotium" (*Journ. Linn. Soc.*, 1886); "On a New Species of *Rhipilia*" (*ibid.*); "On *Boodlea*, a New Genus of *Siphonocladaceæ*" (*Journ. Linn. Soc.*, 1890); The Distribution of Marine Algæ in Space and Time." (*Trans. Biol. Soc.*, Liverpool, 1891); "On a Fossil Alga belonging to the Genus *Caulerpa*, from the Oolite" (*Phycological Memoirs*, 1892); "On a New Species of *Caulerpa*, with Observations on the Position of the Genus" (*Trans. Linn. Soc.*, 1891); "On the Structure of *Dictyosphæria*" (*Phycological Memoirs*, 1892); "A Comparison of the Marine Floras of the warm Atlantic, the Cape of Good Hope, and the Indian Ocean" (*ibid.*); "On *Halicystis* and *Valonia*" (*ibid.*). Author of several articles in the "Encyclopædia Britannica," including "Fungi" and "Vegetable Parasitism." Joint author, with Mr. A. W. Bennett, M.A., of "A Handbook of Cryptogamic Botany," 1889; with Mr. Boodle, of Memoirs on "The Structure of *Spongocladia*" (*Annals of Botany*, 1888); "A Structural and Systematic Account of *Struvea*" (*ibid.*); "A Systematic and Structural Account of *Avrainvillæa*" *Journ. Bot.*, 1889); and, with Miss Barton, "The Structure and Systematic Position of *Chantransia*" (*Linn. Soc.*, 1891).

Supplementary Certificate.—Keeper of Botany, British Museum (Natural History). Author of "A Comparison of the Arctic and Antarctic Marine Floras" (with Miss Barton) (*Phycological Memoirs*, part iii.); "A New Part of Pachytheca" (*ibid.*); "On the Reproduction of some Marine Diatoms" (*Proc. Roy. Soc. Edin.*, 1897); "Introduction to the Study of Seaweeds," 1895.

FRANCIS HENRY NEVILLE,

M.A., College Lecturer. Fellow and Lecturer in Natural Science, Sidney College. Fifteenth Wrangler, 1871. Author of "Recent Progress in the Study of Alloys" (*Science Progress*, vol. iv. Nos. 20, 21); joint author with Mr. C. T. Heycock of the following:—"On a Simplified Form of Apparatus for Determining the Density of Ozone" (*Proc. Camb. Phil. Soc.*, vol. v.); "Lowering of the Freezing Point of Tin by the Addition of other Metals" (*Proc. Chem. Soc.*, No. 65, 1889); "Lowering of the Freezing Point of Sodium by the Addition of other Metals" (*Trans. Chem. Soc.*, vol. lv., 1889); "Molecular Weights of Metals when in Solution" (*ibid.*, vol. lvii.); "Freezing Point of Triple Alloys of Gold, Cadmium, and Tin" (*ibid.*, vol. lix.); "Lowering of the Freezing Points of Cadmium, Bismuth, and Lead, when alloyed with other Metals" (*ibid.*, vol. lxi.); "Isolation of a Compound of Gold and Cadmium" (*ibid.*); "Freezing Point of Alloys, in which Thallium is the Solvent" (*ibid.*, 1894); "Freezing Point of Triple Alloys" (*ibid.*); "On the Determination of High Temperatures by means of the Platinum Resistance Pyrometers" (*ibid.*, 1895).

H. ALLEYNE NICHOLSON,

M.D. (Edin.), D.Sc., Ph.D., F.G.S. Regius Professor of Natural History in the University of Aberdeen. Swiney Lecturer on Geology in the British Museum, 1877-81, 1890-94. Formerly Professor of Natural History in the University of Toronto, 1871-74; afterwards in the University of St. Andrews, 1875-82. Has devoted himself specially to the study of Palæontology. The following are the titles of some of the more important of his numerous published contributions:—"Manual of Palæontology" (third edition); "Invertebrata," 1889; "Monograph of the British Stromatoporoids)," 4to, 234 pp., 28 plates, 1885-92; "The British Graptolitidæ," 1872; "The Palæozoic Tabulate Corals," 1879; "On Monticulipora and its Subgenera," 1881; "Reports on Palæontology of the Province of Ontario," 1874-75; "Silurian Fossils of Girvan," 1881 (jointly with R. Etheridge, jun.); "Bibliography of N. American Invertebrate Palæontology" (with Prof. C. A. White), 1878; "Report on Silurian and Devonian Fossils of State of Ohio," 1875. He has also published numerous separate memoirs on the Graptolitidæ, the Stromatoporoids, the Palæozoic Corals, the Monticuliporoids, the Palæozoic Polyzoa, and certain obscure

organisms which contribute largely to form some palæozoic limestones. He has likewise contributed largely to our knowledge of the structure and fossils of the palæozoic rocks of the Lake District of the North of England by his "Essay on the Geology of Cumberland and Westmoreland," 1868; "On the Strata and their Fossil Contents between the Borrowdale Series and the Coniston Flags" (*Quart. Journ. Geol. Soc.*, 1867), jointly with Prof. Harkness; "Additional Observations on the Geology of the Lake District" (*ibid.*, 1866); "Relations between the Skiddaw Slates and the Green Slates and Porphyries of the Lake District" (*Geol. Mag.*, 1869); "On the Lower Portion of the Green Slates and Porphyries of the Lake District" (*Quart. Journ. Geol. Soc.*, 1871); "On the Occurrence of a New Fossiliferous Horizon in the Ordovician Rocks of the Lake District" (*Geol. Mag.*, 1888, conjointly with J. E. Marr); "On the Stockdale Series of the Lake District" (*Quart. Journ. Geol. Soc.*, 1888, conjointly with J. E. Marr); "On the Cross Fell Inlier" (*ibid.*, 1891, jointly with J. E. Marr). Prof. Nicholson was awarded the Lyell Medal by the Council of the Geological Society in 1888, "as a mark of appreciation of his valuable researches among the older palæozoic rocks, both in the Old and the New World, and of his continued and patient investigations into the organisation of some of those obscure forms of life which abounded at the period of the deposition of those rocks" . . . "his researches have given him a high place among Palæontologists," whilst as a teacher and lecturer he is most successful.

JOHN MILLAR THOMSON,

F.R.S.E., F.I.C. Secretary of the Chemical Society. Professor of Chemistry and Lecturer on Photography, King's College. Professor of Chemistry, Queen's College, London. Author of the following original papers:—"The Composition and Properties of Ancient Glass from Tombs in Cyprus" (*Proc. Phil. Soc.*, Glasgow, 1870); "The Composition of certain Double Salts of Nickel and Cobalt in their relation to Dichroism" (*Brit. Assoc. Rept.*, 1877); "Action of Isomorphous Salts on Supersaturated Solutions of other Salts" (*Journ. Chem. Soc.* 1879); "Action of Constituent Salts on Supersaturated Solutions of Double Salts and Mixtures" (*ibid.*, 1882). Author of the following published lectures and papers:—"The Position of Chemistry in a Technical Education" (*Journ. Soc. of Arts*, 1878); "Solution and Crystallisation" (Glasgow Science Lecture Association, 1879); "The Composition and Properties of certain Pigments" (Cantor Lectures, *Journ. Soc. of Arts*, 1885); "Suspended Crystallisation" (*Proc. Roy. Inst.*, 1886); "The Chemistry of Putrefaction and Antiseptics" (Cantor Lectures, *Journ. Soc. of Arts*, 1887). Distinguished as a lecturer and teacher in Chemistry.

FREDERICK THOMAS TROUTON,

Sc.D. (Dubl.), M.A. Assistant to Erasmus Smith's Professor of Natural Philosophy in the University of Dublin. Teacher of Experimental Physics. Discovered the law connecting the latent heat of vaporisation and molecular weights of bodies known as "Trouton's law" and experimentally determined the directions of vibration of electric and magnetic force in plane polarised light. He has made other important observations on the phase of secondary waves and on the influence of the size of the reflector in Hertz's experiment. Author of:—"On Molecular Latent Heat" (*Phil. Mag.*, vol. xviii.); "Repetition of Hertz's Experiments and Determination of the Direction of the Vibrations of Light" (NATURE, vol. xxxix.); "Experiments on Electromagnetic Radiation, including some on the Phase of Secondary Waves" (NATURE, vol. xl.); "Multiple Resonance obtained with Hertz's vibrations" (NATURE, vol. xli.); "On the Acceleration of Secondary Electromagnetic Waves" (*Phil. Mag.*, vol. xxix.); "The Influence of the Size of Reflector in Hertz's Experiment" (*Phil. Mag.*, vol. xxxii.); "Some Experiments to Determine Wave Velocity in certain Dielectrics" (*Rept. Brit. Assoc.*, 1890); "On Thermo-Electric Currents in Single Conductors" (*Proc. Roy. Dubl. Soc.*, 1886); "On Temporary Thermo-currents in Iron" (*Rept. Brit. Assoc.*, 1889); "On the Motion under Gravity of Fluid Bubbles through Vertical Columns of Liquid of a Different Density" (*Proc. Roy. Soc.*, vol. liv.); "On the Motion of a Body near Points of Unstable Equilibrium and on the same when capable of Internal Vibration" (*Proc. Roy. Dubl. Soc.*, 1888); "On a convenient Method of obtaining any required Electrical Potential for Use in Laboratory Teaching" (*ibid.*); "On the Control Supply Pipes have on Reeds" (*ibid.*); "A Coefficient of Abrasion as an Absolute Standard of Hardness" (*Rept. Brit. Assoc.*, 1880); "On the Use of a Permanently Magnetised Core in a Telephone" (*Phil. Mag.*, vol. xxxiv.); "On Ohm's Law in Electrolytes" (*Rept. Brit. Assoc.*, 1887–88), jointly with Prof. Fitzgerald; "A Method of Determining the Specific Induction Capacity of Dielectrics" (*Phil. Mag.*, vol. xxxiii.), jointly with Mr. W. E. Lilly.

HERBERT HALL TURNER,

M.A., B.Sc. Formerly Fellow of Trinity College, Cambridge. Savilian Professor of Astronomy, Oxford. Secretary to the Royal Astronomical Society. Late Chief Assistant at the Royal Observatory, Greenwich, 1884–94. Author of various papers, among which may be mentioned: "On the Correction of the Equilibrium Theory of Tides for the Continents" (with Prof. G. H. Darwin) (*Proc. Roy. Soc.*, vol. l.); "Report of Observations of the Total Solar Eclipse of August 29, 1886" (*Phil. Trans.*); "On Mr. Edgeworth's Method of Reducing Observations relating to Several Quantities (*Phil. Mag.*, vol. xxiv.); "On Mr. Marth's Intersects" (*Monthly Notices*, vol. xlvi.); "Observations for Coincidence of Collimator at Royal Observatory, Greenwich" (*ibid.*, vols. xlvi. and liii.); "On the Variations of Level and Azimuth of the Transit Circle at Royal Observatory, Greenwich" (*ibid.*, vol. xlvii.); "On the Longitude of Paris" (*ibid.*, vol. li.); "On Stellar Photography" (*ibid.*, vols. xlix. and lix.); "On the R.-D. Discordance" (*ibid.*, vols. liii., liv., and *Memoirs Roy. Astron. Soc.*, vol. li.); "On New Forms of Levels" (*Monthly Notices*, vol. lii.); "Comparison of the Cape (1880) and Greenwich (1880) Star Catalogues" (*Memoirs Roy. Astron. Soc.*, vol. li.); "On the Reduction of Measures of Photographic Plates" (*Monthly Notices*, vol. liv.).

EDWARD JAMES STONE, F.R.S.

THE distinguished astronomer, whose name stands at the head of this notice, and whose loss will be regretted in many scientific circles, played a very prominent part in the history of astronomy during the last forty years. Although he took an active, and often a foremost, place in all the astronomical problems that have aroused attention during this period, he was more conspicuously attached to the astronomy of position, and it was by his devotion to meridian observations that his reputation was mainly won. The early training which he received under Airy, at Greenwich, whither he went on leaving Cambridge in 1860, contributed to this choice. At that time the results obtainable by photography and spectroscopy were quite undeveloped, and the lines on which the Greenwich Observatory then worked were such as to ensure a devotion to accuracy, and the appreciation of the value of star catalogues. All who have since had occasion to use the star places which Mr. Stone published, whether from the Cape, or from the Radcliffe Observatory, have reason to be grateful for that training, which, resulting in his adherence to the methods that he early acquired, led to the production of such admirable work.

In connection with his meridian observations, Mr. Stone had, from time to time, published memoirs on the value of the constants of nutation and refraction, which, though they have not displaced the values assigned by other astronomers, have yet testified to his industry and illustrated his power of conducting a searching discussion into large masses of observations, possessing varying degrees of accuracy. He also largely identified himself with inquiries into the proper motions of stars, the systematic differences between stellar catalogues, the motion of the solar system in space—all questions which demand long numerical calculations, and the values of whose final results depend upon the maintenance of rigorous accuracy in the computations.

In striving to estimate the loss to science caused by the death of the Radcliffe Observer, we give prominence to his meridian work. We recognise the fact that the old

school of astronomy has lost an exponent whom it is not easy to replace. But it would be an injustice to his memory to forget that he showed at times considerable power of originality. His work on such questions as that of the Solar Parallax is deservedly well appreciated. Thirty years ago the problem of the sun's distance occupied a very different position to what it does now. Encke's value, obtained from the discussion of the Transits of Venus of 1761 and 1769, long used without question or hesitation, was beginning to lose its authority before the tests of more rigorous analysis, and the adoption of methods better suited for the determination of this fundamental constant. Stone, by his investigation of the observation of Mars in the opposition of 1862, contributed in no small measure to increase the suspicion which was hovering around the old value of 8″·58. With his attention drawn to this subject, he next reviewed the evidence on which this value was based. With better knowledge of the longitudes of the observing stations, and with possibly a more judicious interpretation of the observer's remarks, he was able to give not only greater accordance to the various observations, but to obtain a result more nearly equal to that derived from other sources of information. For this work he was awarded the gold medal of the Royal Astronomical Society, the President contending that Mr. Stone had shown, beyond all doubt, "that the method pursued by his illustrious countryman Halley, when fairly treated, is capable of furnishing a value of the Solar Parallax commensurate in precision with the expectations formed of it." The history of subsequent transits has, perhaps, not borne out this favourable view, expressed in 1869; but Stone's loyal and persistent efforts to deduce from the transits all that they were capable of giving are shown, by the part he took, both in 1874 and 1882. In the former year he was Her Majesty's astronomer at the Cape of Good Hope, and contributed much to the organisation of the various expeditions to the Southern Hemisphere. By the time of the second transit in 1882, he had succeeded to the direction of the Radcliffe Observatory on the death of the Rev. Robert Main, and there he trained the selected observers in methods suggested by the experience gained in 1874. After the transit, the whole of the observations were reduced under his immediate superintendence, with results too well known to need further mention.

It is needless to say that Mr. Stone's direction of the Radcliffe Observatory during the last twenty years was characterised with vigour and general success. Two important star catalogues were issued under his superintendence. The meteorological department received considerable attention, and Mr. Stone, in addition, accepted a seat at the Board of the Meteorological Council. In another matter, which one naturally wishes to pass over very briefly, his researches were not so successful, but have shown him the victim of a strange paradox. The comparatively large discrepancies which exist between the observed longitudes of the moon and those computed from Hansen's tables, he sought to explain by attributing their origin to the substitution of Le Verrier's tables of the sun for those of Carlini. This slight breach of continuity in the record of mean solar time, produced by the introduction of the newer tables into the Nautical Almanac was, he urged, the cause of the gradual increase in the error of Hansen's tables; and though many eminent authorities, including Profs. Adams and Newcomb, endeavoured to convince him of his error, he supported his views to the last, and regularly published the errors of the lunar tables, as derived from the Radcliffe observations, after applying to the mean time of observation a correction based upon his theory.

On two occasions Mr. Stone observed a total eclipse of the sun; the first at Klipfontein in Namaqualand, and last summer he accompanied Sir George Baden Powell to Nova Zemlya, where he was again successful in watching the phenomenon. But to the physical side of astronomy he gave little attention; nor is the Radcliffe Observatory equipped in a manner to make such observations possible.

Mr. Stone received many acknowledgments of the value of his work. Besides being a Fellow of the Royal Society, he had been President of the Royal Astronomical, and held other offices in connection with the same Society. He received a Doctor's degree from the University of Padua, and besides the Astronomical Society's medal, to which allusion has been made, the French Academy bestowed upon him the Lalande medal, as a testimony to the value of his Southern Catalogue of 12,500 stars. He died on Sunday, May 9, at his Oxford residence, aged sixty-six. W. E. P.

NOTES.

THE first of the two annual conversaziones of the Royal Society was held yesterday evening, as we went to press.

THE University of Toronto has decided to confer the degree of LL.D. upon Lord Lister, Lord Kelvin, Lord Rayleigh, and Sir John Evans.

THE fifteen candidates selected on Thursday last by the Council of the Royal Society to be recommended for election into the Society are:—Dr. R. Bell, Sir W. H. Broadbent, Bart., Dr. C. Chree, Mr. H. J. Elwes, Dr. J. S. Haldane, Prof. W. A. Haswell, Prof. G. B. Howes, Dr. F. S. Kipping, Prof. G. B. Mathews, Mr. G. R. Milne Murray, Mr. F. H. Neville, Dr. H. A. Nicholson, Prof. J. M. Thomson, Dr. F. T. Trouton, and Prof. H. H. Turner. Following our usual custom, we print in another part of this issue the certificates of the candidates selected.

DR. C. LE NEVE FOSTER has given men of science cause to be proud that he is one of them. On Saturday morning last he was at the Snaefell lead mine, Isle of Man, in his capacity of Her Majesty's Inspector of Mines. An explosion had occurred there on the preceding Monday, and Dr. Foster's object was to ascertain whether it was possible to recover the body of a miner remaining in the workings. Lighted candles sent down to test the atmosphere burnt brightly at 115 fathoms, but were extinguished at 130 fathoms. From these indications it was considered safe to go down a certain distance; so a party, consisting of Dr. Foster, Mr. G. J. Williams (Assistant Inspector of Mines), Captain Reddicliffe, Captain Kewley, and eight others descended the shaft. The air below was tested, and found to be poisonous; but as the party was only a few feet above the body of the miner, Captain Kewley went two or three steps down a ladder, and attempted to catch the man's clothing with grappling-irons. The commotion caused by his swinging to and fro appears to have disturbed the gas, for Captain Kewley was at once overcome, and had to be hauled back to the landing. He was put into the box, and the box was going up to the surface, when it became jammed, and for over an hour could not be moved. Meanwhile, Dr. Foster and those of his companions who could not climb to the surface were below suffering from the influence of the poisonous gas—apparently carbon monoxide. During this time, when death seemed to be very near, Dr. Foster made copious notes of his sensations. He commenced writing at 2 p.m., and continued until 3.30, when he was brought to the surface, he being the last to go up. Some of the men were unconscious when brought to the surface, and others arrived in an excited and hysterical condition. The record obtained by Dr. Foster will be a most valuable physiological document,

for, judging from the extracts given in the daily press, the gas to which the exploring party was subjected has a peculiar effect upon the mind. As the minutes passed by, Dr. Foster's notes became more and more disjointed, and it is hard to believe that he knew exactly what he was writing towards the end. The following are a few of the notes written while he believed himself to be dying:—"I fear we are all dying. No help coming. . . . The box does not come. In spite of all our ringing for help, it will not come. Captain Reddicliffe is struggling. No real pain. Good-bye. I feel as if I were sleeping. Again, good-bye all! 2.15 p.m.—We are all done. Oh, for the box! It is held in the shaft. . . . It is really like a bad dream. No pain. No pain. For the benefit of others, no pain. . . . 2.25 p.m.—Two of the party are all right. I think they are ringing. When is help coming? The box is gone. Four new men are coming. I don't feel bad. It is strange to write notes while we are dying. What a lot I have written! Captain Reddicliffe is about the worst. I think he will go first. While there is life there is hope. Good old proverb! Send a note for more brandy. Send for more help. The box has just gone up with Reddicliffe. Williams goes next—he has a capital heart. 2.45.—I have written pages. Kewley is a good fellow. There is life in the old horse yet. I feel as if I could sing. God is helping us; he has heard our prayer. My turn to go." Arriving at the surface, and getting out of the box, Dr. Foster, note-book in hand, though weak and staggering, made the entry stating the time at which he got to the top. His last entry was:—"Dr. Miller says I must be quiet, but I won't." The pathetic side of this record, made by one who had almost crossed the dark valley, but was happily brought back to tell his tale, touches all of us. We admire Dr. Foster for his coolness in time of danger, and for remaining behind until all his party had been rescued. The world could ill spare a man with such sterling qualities, and science would grieve to lose an investigator who devoted what seemed to be his last moments to extending knowledge "for the benefit of others." We offer to Dr. Foster our heartiest congratulations upon his rescue, and we trust that he may never again have to repeat his terrible experience.

THE next annual meeting of the Australasian Association for the Advancement of Science will commence on January 6, 1898.

M. SOUILLART, Professor of Astronomy in the University of Lille, has been elected a Correspondant in the Section d'Astronomie of the Paris Academy of Sciences, in succession to the late Prof. Gyldén.

A REUTER correspondent at St. Petersburg states, on the authority of the *Novoe Vremya*, that an expedition is to be sent by the Russian Geographical Society and Academy of Sciences to study the geography and natural history of the Khanates of Roshan, Shignan, and Darwaz.

WE learn from *Science* that Miss Alice Bache Gould has given $20,000 to the National Academy of Sciences as a memorial to her father, the distinguished astronomer, Dr. B. A. Gould. It will be known as the Gould Fund, and the income will be used to promote researches in mathematics and astronomy.

A COMPLIMENTARY banquet will be given to Lord Lister at the Café Royal, Regent Street, on May 26, by his former house-surgeons, clerks, and dressers. A complete list is being prepared of those who have been closely associated with Lord Lister in his teaching career, which extends over a period of thirty-two years—from 1861 to 1893.

THE vehicles entered for the *Engineer* 1100 guineas road carriage competition will be examined by the judges on Friday and Saturday, May 28 and 29, at the Crystal Palace. The long-distance run, between the Crystal Palace and Post Office in Birmingham, will begin on Tuesday, June 1. The distance over the whole course, upon which the time allowance referred to in the conditions will be computed, has been fixed by the judges at 263 miles.

THE Prussian Academy of Sciences have made a grant of 1100 marks to Prof. Dr. Paschen, Hanover, for the study of the energy in the spectra of dark bodies; and of 1000 marks to Dr. N. Herz, now at Heidelberg, for the reduction of observations made at the Kuffner Observatory, Vienna. Dr. O. Bütschli, Heidelberg, and Dr. A. Weismann, Freiburg, have been elected corresponding members of the Academy.

THE Engineering Conference, organised by the Institution of Civil Engineers, will be opened at 10.30 a.m. on Tuesday, May 25, in the large hall of the Westminster Town Hall, when the President, Mr. J. Wolfe Barry, C.B., F.R.S., will deliver a short address to the combined Sections. The several Sections will then proceed to the consideration of their respective business in the Town Hall and the Guildhall. The meetings will be continued on the 26th and 27th, at the same places, at 10.30 each day.

MR. ROBERT C. L. PERKINS, B.A. of Jesus College, Oxford, who has been for several years engaged on behalf of the Joint Committee appointed by the Royal Society and the British Association for investigating the zoology of the Sandwich Islands, has now returned to England, and, we rejoice to say, is in good health, notwithstanding all the hardships he has undergone. A very instructive paper by him, on "The Introduction of Beneficial Insects into the Hawaiian Islands," will be found in NATURE of March 25 last (p. 499).

THE summer meeting of the Anatomical Society of Great Britain and Ireland will be held this year in Dublin, on June 9, 10, and 11. A very large number of members have promised to attend, and the meeting will be remarkable on account of the numerous distinguished continental anatomists who are expected to take part in the proceedings. Amongst these are Prof. His, Leipzig; Prof. Waldeyer, Berlin; Prof. Stieda, Königsberg; Prof. Spalteholtz, Leipzig; Prof. Disse, Marburg; Prof. Klaatsch, Heidelberg; Dr. Otis, Boston; Prof. Leboucq, Ghent; Prof. van der Stricht, Ghent; Prof. van Gehuchten, Louvain; Prof. Retzius, Stockholm; Dr. Kaestner, Leipzig; Dr. de Bruyne, Ghent; and Dr. Fröhse, Berlin. One of the features of the meeting will be an address to be delivered by Prof. His in the new theatre of the Royal Dublin Society, under the auspices of the Royal Academy of Medicine in Ireland. The subject which he has chosen for this address is the "Development of the Brain, Cord and their Nerves." The ordinary meetings of the Society will be held in the Anatomy School of Trinity College.

MR. LAWRENCE BRUNER, of the University of Nebraska, has (says the *American Naturalist*) sailed to Argentina to study the ravages of the locusts, which have recently developed into a terrible pest, certain regions being completely devastated by them. The Argentine Government has granted 400,000 dols. for relief, and a syndicate of business men have raised funds to employ Mr. Bruner to investigate the entomological aspects of the subject.

WE regret to have to include in this week's obituary the names of Prof. Legrand des Cloizeaux, member of the Paris Academy of Sciences, and distinguished for his works on crystallography and the optical properties of minerals; Dr.

H. V. Carter, for many years professor of anatomy and physiology in the Grant Medical College at Bombay; Mr. Walter Rivington, author of a large number of papers on anatomical and surgical subjects, and Fellow of the University of London; Dr. Traill Green, formerly professor of chemistry at Lafayette College; Dr. E. Russow, formerly professor of botany at Dorpat; Dr. Ch. Scholz, professor of geodesy in the Polytechnikum at Delft; and Dr. Traill Green, one of the few surviving founders of the American Association for the Advancement of Science, first president of the American Academy of Medicine, and author of the "Floral and Zoological Distribution of the United States."

AT the Royal Institution, on Tuesday, May 25, Dr. Ernest H. Starling will begin a course of three lectures on "The Heart and its Work." The evening discourse on Friday, May 21, will be delivered by Lord Kelvin, his subject being "Contact Electricity of Metals." The Friday evening discourse next week (May 28), will be delivered by Prof. H. Moissan (Directeur, Laboratoire de Chimie Minérale à l'École Supérieure de Pharmacie, Membre de l'Académie des Sciences, Paris), who will lecture in French on "The Isolation of Fluorine" (with experiments). On Friday, June 4, Mr. W. H. Preece, C.B., F.R.S., will lecture on "Signalling through Space without Wires"; and on June 11, Mr. William Crookes, F.R.S., will deliver the last of the Friday evening discourses for the year: his subject will be "Diamonds."

THE Board of Agriculture have issued an order which prohibits the importation of dogs into Great Britain from any other country (except Ireland and the Isle of Man) otherwise than in accordance with certain provisions set forth. The order takes effect on September 15, 1897. After that date no dog may be landed in Great Britain from any other country without a licence from the Board of Agriculture, application for which is to be made to the Secretary of the Board. We agree with the *British Medical Journal* that this action of the President of the Board of Agriculture must be regarded as a step in the right direction. Any scheme for the extermination of rabies and its dependent hydrophobia which does not deal with importation of dogs must be incomplete. It is pointed out, however, that if simultaneous action as to the enforcement of muzzling and importation regulations be not taken in Ireland, it is to be feared that the present attempt to exterminate rabies from Great Britain may fail. A general muzzling order and the present importation order should now be made applicable to Great Britain and Ireland; for, without further assurance of freedom from rabies than can now be given, it cannot be regarded as absolutely safe to introduce without restriction dogs from one part of the United Kingdom to another.

THE provisions of the new Dingley Tariff Bill, taxing books, apparatus, and antiquities imported into the United States, raised such a storm of protests from scientific men and institutions of learning, that they appear to have been abandoned; for we learn from *Science* that the Tariff Bill, as amended by the Senate Finance Committee, includes the following additions, among others, to the list of objects which may be imported free of duty: books, maps, music, engravings, photographs, etchings and charts, printed more than twenty years before the date of importation; all hydrographic charts and scientific books devoted to original scientific research, and publications issued for their subscribers by scientific and literary associations, or publications of individuals for gratuitous private circulation, and public documents issued by foreign Governments; books, maps, &c., especially imported, not more than two copies in any one invoice, for the use of any society or institution established solely for religious, philosophical, educational, scientific or literary purposes, or for the encouragement of the fine arts, or for the use of any college, school or public library, and not for sale; paraffin, philosophical and scientific apparatus for schools, libraries and societies; professional books, implements and instruments, and tools of trade or occupation in the actual possession at the time of persons arriving in the United States.

AT the Leathersellers' Hall on Wednesday, May 12, a large company assembled at a conversazione; the Master, Dr. W. H. Perkin, F.R.S., and Wardens receiving the guests. The numerous and varied nature of the exhibits added great interest to the occasion; and not only were scientific discoveries, mostly of recent date, shown, but the industry associated with the name of the Company was well illustrated. Several very interesting objects were also sent from the different branches of the City and Guilds Institute, a creation of the City Companies of which they may well be proud. The following is a brief summary of the exhibits:—Specimens illustrative of the manufacture of coal-tar colouring matters, and their application, Dr. W. H. Perkin. Among Prof. Ayrton's exhibits may be mentioned an ingenious water model illustrating the retardation of signals in a submarine telegraph cable, a mechanical model illustrating the principle of duplex telegraphy, and some instruments employing the magnifying spring devised by Profs. Ayrton and Perry. Prof. Roberts-Austen exhibited an electric furnace in operation, throwing an image of the interior on a screen. A most interesting collection of specimens of artistic bookbindings was exhibited by Mr. H. B. Wheatley. Photography in colours, and various processes of photographic reproduction were largely represented. Sir H. T. Wood exhibited illustrations of the Dansac-Chassagne process of colour photography. The Autotype Company showed various pictures reproduced by their process, and Mr. Ives gave lantern demonstrations of the Kromskop. Other exhibits included specimens from the Leathersellers' tanning and dyeing school; maps, diagrams, &c., made by the boys in Colfe's school, which is under the management of the Company; specimens in illustration of research work now in progress in the chemical department of the Central Technical College, and several others too numerous to mention in this brief summary.

TWO young oak-trees were planted on May 11, at Cowthorpe, near Wetherby, to commemorate the celebrated tree which stands there still, but is greatly decayed, and may not endure much longer. The old tree, as every one knows, girths more than fifty feet, and is in that respect probably the largest oak in the world. The young oaks have been raised from acorns taken from the old tree by Mr. John Clayton, of Bradford, in 1893. The late Mr. Montagu, of Ingmanthorpe, approved of this method of perpetuating the memory of the wonderful tree.

PROF. JOHN MILNE, F.R.S., has sent us a list of ninety-three earthquakes observed by him at Shide, Isle of Wight, from June 14, 1896, to March 1897. The Greenwich mean time of each disturbance is given, and the character and intensity of each record is stated.

IN the *Annales de la Société Belge de Microscopie*, M. A. Lemeere records the results of an experiment in establishing a "peripatetic laboratory" for the zoological and botanical students of the University of Brussels during the summer vacation.

WE learn from the *American Naturalist* that President Cleveland had, by proclamation, set apart thirteen new forest reserves in the United States, representing an area of more than 21 million acres. This increases the total reserve forest land in the West to 39 million acres. The new reserves include all the central portion of the Black Hills of South Dakota, the Big Horn Mountain Range in Wyoming, the Jackson Lake country south of the National Park in Wyoming, all the Rocky Mountains of Northern Montana, a valuable forest region in Northern

Idaho, the principal part of the Bitter Rest Mountain region in Montana and Idaho, the Cascade Mountains of the Yosemite National Park, the San Jacinto Mountains in Southern California, and the Uintah Mountains in Northern Utah. The selection of these forest lands was made by the Commission appointed by the National Academy of Sciences. Strong opposition has been made to the appropriation by private owners.

"THE FLORENTINE CRICKETS" is the title of an interesting essay in the folk-lore of these insects, by Sophia Beale, in *The Reliquary and Illustrated Archæologist* (vol. iii., 1897, p. 65). In Florence, at the Festival of the Ascension, "all the inhabitants prance about carrying little cages dangling from their fingers. It is an ancient custom, its origin is as vague as the date of its institution, but all agree that the little beasts, which are imprisoned in the cages, are a species of talisman—an omen for good or evil to the person who possesses them."

THE re arrangement of the Free Public Museums of Liverpool is rapidly progressing under the administration of Dr. H O. Forbes. He recognises that Anthropology, or rather that portion of it which is now sometimes termed Anthropography, is a branch of Biology, and so he has devoted a gallery to an exposition of the main races of men at the end of the series of galleries allocated to the Vertebrates. The collection forms an instructive introduction to Ethnology, and we hope that he will be able to make it more complete as opportunities present themselves. The Ethnographical collections, which are in another part of the building, are well displayed, and contain many interesting objects. These collections, together with the well-known Archæological treasures in the Museums, afford a good foundation for Anthropological studies in Liverpool.

THE *Records* of the Geological Survey of India (vol. xxx. part 1) contain the full account of a palæo-botanical discovery which has been made independently and simultaneously in India and in South Africa. The fossil plant-structure long known under the name of *Vertebraria* is now shown to be nothing else than the rhizome of the fern *Glossopteris*, which has given its name to the remarkable flora of the Gondwana-beds of the southern hemisphere. The specimens figured by Mr. R. D. Oldham show the association of leaf and rhizome clearly, as also do those described by M. Zeiller from near Johannesburg.

M. ÉMILE MÜLLER, Professor in the Lycée of Tashkent, sends to the Société de Géographie an extract from an account of an expedition on the Pamirs by Messrs. Olifsen and Filipsen, Danish officers, describing a remarkable tribe of dwarfs discovered in a little-known part of this region. The men of this tribe are invariably of exceedingly small stature, and a similar dwarfish habit extends to the domestic animals; the oxen of this district are about the size of donkeys, donkeys are no bigger than dogs, while goats and sheep are mere miniatures. In the original account published in the Russian journal, *Pravitelstvenni Viestnik*, for January 11/23, the explorers ascribed these anomalies to the exceptional environment and the arrested development due to the great scarcity of food. The tribe in question is entirely savage, badly armed, and wholly occupied in hunting; their religion is a species of fire-worship.

AMONG recent papers dealing with optical theories in general, we would call attention to Herr Paul Glan's interesting series of theoretical investigations on elastic bodies and light, in *Wiedemann's Annalen*, where results are found agreeing remarkably well with those obtained by experiment with Röntgen and ultra-violet rays; to a short paper in the *Berliner Sitzungsberichte*, by Prof. H. Rubens and E. F. Nichols, on the observation of electric resonance in heat rays of great wave-length; to a lengthy memoir, by Prof. G. Quesneville, on the double elliptic refraction of quartz (Paris, Offices of the *Moniteur Scientifique*, 1896), in which the author criticises MacCullagh's theory; and to Prof. Augusto Righi's two papers in the *Atti dei Lincei*, vi. 6—one on the elliptic polarisation of electromagnetic waves and their ellipsoid of polarisation in selenite, the other dealing with the absorption of electro-magnetic waves.

PROF. G. O. SARS, who has for many years been specially engaged in the study of the various groups of Crustacea, has in preparation a complete account of the Crustacea of Norway, and his work is now in course of publication by the Bergen Museum. All the known Norwegian species will be described, and will be accompanied by carefully drawn figures of all the forms. Parts iii. and iv. of vol. i., containing descriptions and illustrations of members of five families of Isopods, viz. Anthuridæ, Gnathiidæ, Ægidæ, Cirolanidæ, and Limnoriidæ, have just been issued.

SOMEWHAT late in the season we have received from Mr. Murray a new edition of his "Handbook for Travellers in Lower and Upper Egypt," which has been practically re-written and edited by Miss Brodrick, Prof. Sayce, and Captain Lyons, R.E. It has long been known that the late Sir G. Wilkinson's "Guide" was antiquated, and many of his views and conclusions have for some time past been shown to be untrustworthy, notwithstanding their excellence forty or fifty years ago. Mr. Murray's new work is well printed on thin paper, and takes up less room than the earlier editions; we venture to think that a "Guide" in one volume is always more useful than one in two. We welcome the new maps with which the book is furnished, and every one who takes any interest in hieroglyphics will rejoice that the old wood-blocks of the cartouches of the kings' prænomens and nomens have been replaced by legible hieroglyphic type. A special feature of the book is the Arabic Vocabulary; and although it is hard to understand on what principle the words have been selected, it will, no doubt, be useful to the intelligent visitor to Egypt.

MESSRS. GEORGE HOUGHTON & SON, photographic manufacturers and dealers, have just published a comprehensive illustrated catalogue of photographic apparatus and materials.

MANY chemists have at various times expressed the view that the acid amides, such as acetamide and benzamide, have not the constitution which is usually assigned to them, $NH_2 . R = O$, but are in reality hydroxy-derivatives of the formula $NH = R . OH$. An important contribution to this subject is made in the current number of the *Berichte* by W. Eschweiler, who has succeeded in preparing a new isomeride of glycollamide, $CH_2(OH) . C\left\langle\begin{matrix} O \\ NH_2 \end{matrix}\right.$, which differs entirely in properties from that compound, and appears to be the hydroxy-compound $CH_2(OH) . C\left\langle\begin{matrix} OH \\ NH \end{matrix}\right.$. The new compound is obtained by heating the corresponding nitrile, $CH_2(OH) . CN$, with water to a high temperature, and, like glycollamide, is converted into glycollic acid by the action of alkalis. The author has obtained similar isomerides of a number of other acid amides, the full description of which will be awaited with interest.

THE current number of the *Zeitschrift für Physikalische Chemie* contains a paper, by Prof. Ostwald, on the crystallisation of super-saturated solutions and of super-cooled liquids, which adds considerably to our knowledge of this little-studied subject. The chief difficulty of the experiments is caused by accidental infection of the solutions by particles of solid dust. This may be avoided by a proper choice of substances, and it may then be

proved that crystallisation is only caused by the introduction of a crystal of the substance, or of a strictly isomorphous substance. For example, fused salol (melting point 39°·5) cannot, at ordinary temperatures, be induced to crystallise by any of the usual means; but if a fine thread of glass be lightly drawn over a crystal of salol, it acquires the power of inducing crystallisation in the liquid; it loses it again by exposure to the air for a few minutes, by wiping with soft sheet india rubber, or by warming above 40°. There is, however, only a limited range of temperature below the melting point in which spontaneous generation of crystals is impossible; the liquid is here in stable equilibrium, except with respect to a ready-formed crystal. Ostwald proposes the name *metastable* for this condition. At still lower temperatures, crystals form spontaneously and without the presence of ready-formed nuclei; the equilibrium is here really labile. The analogy between the phenomena observed during the passage from the liquid to the solid condition, and those observed in the passage from gas to liquid, is pointed out. Notwithstanding the very minute quantity of substance required to start the crystallisation, Prof. Ostwald has succeeded in showing that it has a lower limit. The two methods employed (successive dilution with an indifferent solid substance in the way practised by the homœopathists, or evaporation of minute drops of successively more and more dilute solutions of the solid on a platinum wire, and introduction of the residues into the supersaturated liquid) gave practically identical results. With sodium chlorate solution, for example, containing 107 parts of the salt to 100 of water, the smallest quantity of solid, which would still induce crystallisation, was from a millionth to a ten-millionth of a milligram. The fact that a very minute quantity of ammonia alum induces crystallisation of a solution of potassium alum, instead of being itself dissolved, may be explained by supposing that the dissolved salt diffuses into the solid particle as soon as it comes in contact with the solution; a nucleus of the solid potassium alum having been thus formed, it continues to increase. This explanation is in agreement with the facts that only truly isomorphous salts are capable of forming solid solutions, and also that they alone are capable of mutually inducing crystallisation. For the statement and discussion of a proposition, which may be paraphrased as follows, the paper must be consulted. When a system passes from any given condition to a more stable one, it will not pass into the state which, under the circumstances, is the most stable, but into that which is nearest to the original state.

THE additions to the Zoological Society's Gardens during the past week include a White-throated Capuchin (*Cebus hypoleucus*) from Central America, presented by Sir Henry A. Blake, K.C.M.G.; a Pig-tailed Monkey (*Macacus nemestrinus*) from India, presented by Mr. W. B. Orme; an Egyptian Jerboa (*Dipus ægyptius*) from Egypt, presented by Mr. S. Whitehouse; a Kinkajou (*Cercoleptes caudivolvulus*), a Sharp-nosed Crocodile (*Crocodilus acutus*) from Venezuela, a Rough-eyed Cayman (*Caiman sclerops*), two Tuberculated Iguanas (*Iguana tuberculata*), a Black-pointed Teguexin (*Tupinambis nigropunctatus*), a Chequered Elaps (*Elaps lemniscotus*), an Anaconda (*Eunectes murinus*) from Trinidad, two —— Geckos (*Thecadactylus rapicauda*), a Cuvier's Scolecosaurus (*Scolecosaurus cuvieri*), an Agile Lizard (*Mabuina agilis*), three Thick-necked Tree Boas (*Epicrates ceuchris*), four Common Boas (*Boa constrictor*), five Cooke's Tree Boas (*Corallus cookii*), a Mocassin Snake (*Tropidonotus fasciatus*), a Boddaert's Snake (*Drymobius boddaerti*), a —— Snake (*Coronella calligaster*), a —— Snake (*Helicops angulatus*) from the West Indies, presented by Mr. R. R. Mole; an Anaconda (*Eunectes murinus*) from Trinidad, presented by Mr. F. W. Urich; an Indian Pigmy Goose (*Nettopus coromandelianus*) from India, a Laughing Kingfisher (*Dacelo gigantea*) from Australia, a Temminck's Snapper (*Macroclemmys temmincki*) from the Southern United States, deposited; six Mexican Quails (*Callipepla squamata*) from Mexico, purchased; two Egyptian Weasels (*Mustela subpalmata*), eight Shaw's Gerbilles (*Gerbillus shawi*), an Egyptian Jerboa (*Dipus ægyptius*), three Long-eared Hedgehogs (*Erinaceus auritus*), a Grey Monitor (*Varanus griseus*), nine Egyptian Cobras (*Naia haje*), eight Cerastes Vipers (*Cerastes cornutus*), a Rough-keeled Snake (*Dasypeltis scabra*), three Clifford's Snakes (*Zamenis diadema*), two Hissing Sand Snakes (*Psammophis sibilans*), ten Ocellated Sand Skinks (*Seps ocellatus*), four Vinaceous Turtle Doves (*Turtur vinaceus*), two Lesser Pin-tailed Sand Grouse (*Pterocles exustus*) from Egypt, received in exchange.

OUR ASTRONOMICAL COLUMN.

RESOLVING POWER OF TELESCOPES AND SPECTROSCOPES.—In the current number of the *Memorie della Società Degli Spettroscopisti Italiani* (vol. xxvi., 1897), Prof. F. L. C. Wadsworth discusses the question of the theoretical resolving power of optical instruments, distinguishing between four different cases. According to Rayleigh, the theoretical angular resolving power of any instrument having an aperture of width b is

$$a = m\frac{\lambda}{b}$$

where a is the angle between two fine lines or points which can just be separated (a close double, for instance): λ the mean wave-length of the light employed, b the linear aperture of the instrument, and m a constanr, varying according as the aperture is rectangular or circular. The spectral resolution of separation of a spectroscope can be determined from this formula by considering the dispersing train of prisms or gratings as a series of spectral images of the slit of the spectroscope. The four cases which are minutely dealt with are: (1) The resolving power (theoretical) of a spectroscope train for an infinitely narrow slit and monochromatic radiations, *i.e.* infinitely narrow spectral lines. (2) The resolving power (also theoretical) for a wide slit and monochromatic radiations. (3) The resolving power (limiting) for an infinitely narrow slit, but for lines of finite width $\Delta\lambda$. (4) The resolving power (practical) for a wide slit and non-monochromatic radiations, ranging for each line over a small value of $\Delta\lambda$, as in (3). This quantity represents the practical resolving power or purity of the spectrum.

The expression for the spectroscopic resolution for the second case differs from that obtained in the first by the presence of a new factor in the denominator of the former. The existence of this necessitates, as Prof. Wadsworth says, a considerable modification of certain statements based on the old formula of purity. Instead of a continual decrease with increase of slit width, the purity of the spectrum actually increases up to a certain point, and is equal to the theoretical resolving power of the instrument. On a further widening of the slit, the purity begins to diminish, but not so rapidly as previously supposed. This modification of the old idea requires, as he points out, a correction in Schuster's remarks on the practical purity of a bright-line spectrum, which gives the purity as 50 per cent. of the resolving power, and not 75 per cent., as Prof. Wadsworth now finds it must be. Other points of equal interest result from this new discussion, and are dealt with in this paper.

PHOTOGRAPHS OF METALLIC SPECTRA.—An investigation of considerable utility in astrophysics (*Sitzungsberichte der König, Preuss, Akad. d Wiss. zu Berlin*, March 4, 1897) has recently been concluded by Dr. O. Lohse in Potsdam. This consists in the determination of the wave-lengths of the lines in the spectra of cerium, lanthanum, didymium, thorium, yttrium, zirkonium, vanadium, and uranium, for the violet region 400 $\mu\mu$ to 460 $\mu\mu$. The spectra were obtained by photography with a spectroscope fitted with a prism filled with zimmtaethyl, the length of the resulting spectrum between the above wave-lengths measuring 180 mm. Spark spectra alone were investigated, and by means of a gas motor and dynamo a considerable strength of current was obtained. During the experiments it was found that the heat affected to an appreciable extent the refractive and dispersive power of the fluid in the prism, although it was not sufficient to be measurable with delicate thermometric instruments. The definition of the lines was therefore to

some extent not very good; for the same reason, exposures longer than 70 seconds were not deemed advisable. These temperature variations made the measurements of wave-length a more difficult task than would have been the case had they been absent, but Dr. O. Lohse seems to have taken the greatest pains to overcome this point; the measures were based on the solar spectrum, Rowland's normal lines being adopted; while the spectrum of iron was used as a comparison. It is stated that the measures may be generally taken as accurate up to a tenth of an Angström unit (0·01 $\mu\mu$), and only in the cases of very dim or broad lines is this limit exceeded; the intensities are given on a scale of tenths. The communication concludes with tables of the wave-lengths thus obtained.

THE ROYAL GEOGRAPHICAL SOCIETY.

AT the anniversary meeting of the Royal Geographical Society, on May 17, the President, Sir Clements Markham, F.R.S., in place of the usual annual address, gave a review of the progress of British geography during the sixty years of the Queen's reign. The practice of delivering an anniversary address was commenced in 1837 by the then President, Mr. W. R. Hamilton, in the eighth year of the Society. The first presidential address took the form of a survey of the position of geography at the time, and now forms a suitable landmark by which to estimate the advance that has been made. The Ordnance Survey of the British Islands was fairly under way, and that of India was also in progress. Hydrographic surveys were being pursued by British ships in every sea, and the coasts of Africa had been charted. The whole interior of Africa, most of Australia, and immense territories in Asia and South America were absolutely unexplored. The whole science of oceanography, although created by Rennell, had not yet been recognised.

One of the first pieces of geographical research of the Queen's reign was the memorable voyage of Sir James Clark Ross to the antarctic regions in 1839-41, and this may be held to be the only antarctic expedition ever sent out. Of late years the necessity for an antarctic expedition has become more and more urgent, for many reasons, but chiefly because the science of terrestrial magnetism is at a standstill, owing to the absence of any observations in the far south during the last fifty years. The knowledge which would be acquired by such a magnetic survey will not only be of scientific interest, but will also be of practical importance to navigation. Deep-sea soundings, dredgings, temperatures of the ocean at various depths, meteorology, the distribution of marine organisms, are some of the investigations which would be undertaken by an antarctic expedition with reference to the ocean. Equally important objects would be to determine the extent of the south polar land, to ascertain the nature of its glaciation, to observe the character of the underlying rocks and their fossils, and to take meteorological observations on shore.

Since 1893 the most strenuous efforts have been made to induce the Government to send out another naval antarctic expedition, but without result. We have been told that officers cannot be spared from the ordinary routine of the fleet; that times are much changed from the days of the *Challenger's* commission, and are now much more unsettled. It is forgotten that the naval superiority of Great Britain, in the days of St. Vincent and Trafalgar, "lay not in the number of her ships, but in the wisdom, energy, and tenacity of her officers and seamen," and that these qualities are now to be acquired by such special service as is involved in an antarctic expedition. It is forgotten that in the good old times neither war nor the fear of war were any check to the despatch of naval expeditions of discovery. Captain Cook was sent on his third voyage at a time when France, Spain, Holland, and the American insurgents were all vainly banded together for our destruction. In the midst of the French revolutionary war, Captain Vancouver was calmly surveying the intricate straits and sounds of New Albion, and Captain Flinders was exploring the shores of Australia.

The duty which will not be undertaken by the Government, will now receive the special attention of the Society, which will not appeal in vain for co-operation to the patriotism and energy of private individuals in Great Britain, or to the Governments in Australasia.

In the arctic regions Englishmen have discovered the whole of the American side from Bering Strait to the north coast of Greenland, and have explored the intricate system of channels and straits which separate the numerous islands. They have thus thrown open to the knowledge of the world a vast amount of information in all branches of science, and have especially taken the largest share in preparing for the solution of the polar problem. Dr. Nansen, by his memorable drift of the *Fram*, has supplied what was needed to complete the means of comprehending what had previously been a mystery. For this great service to geography Nansen has received a special gold medal from the Society; and he has rendered ever memorable, in arctic history, the sixtieth year of the Queen's reign. It saw the solution of the north polar problem.

The main points in the history of the exploration of each continent were touched upon, and the part taken by the Society in the work made plain, the President summing up the results as follows.

"When we contemplate these immediate consequences of our geographical work, it will, I am sure, be felt by all who are connected with this great Society, that it occupies a position of national importance, a position which entails most serious duties and heavy responsibilities. It is our privilege to render frequent services to several departments of the Queen's Government; to take the lead in numerous enterprises, many of which are eventually recognised, in their results, as involving considerable benefits to the nation; and to prepare the means, by our great collections of books and maps, and by the facilities we can give for instruction, for others, including the authorities under Imperial guidance, to follow in our footsteps."

As regards the new departures in the work of the Royal Geographical Society, the President mentioned the institution of a diploma for proficiency in practical astronomy and surveying, and the according of a large measure of support to Mr. Mackinder's scheme of a London School of Geography.

The Royal medal awarded to Dr. G. M. Dawson was handed to Sir Donald Smith, the High Commissioner for Canada; that awarded to M. P. P. Semenoff was given to M. Lessar, of the Russian Embassy. The Danish Minister received the awards given to Dr. Thoroddsen and Commander Ryder, while Lieutenant Seymour Vandeleur received the Murchison grant in person.

THE IRON AND STEEL INSTITUTE.

THE annual spring meeting of the Iron and Steel Institute was held on Tuesday and Wednesday of last week, in the theatre of the Institution of Civil Engineers. There were twelve papers down on the list, as follows:—"On the Permeability of Steel-making Crucibles," by Prof. J. O. Arnold and F. K. Knowles; "On the Practice of the Combined Open-Hearth Process of Bertrand and Thiel," by E. Bertrand; "On the Agricultural Value of Sulphate of Ammonia from Blast-Furnaces," by F. J. R. Carulla; "On the Specific Heat of Iron," by Prof. W. N. Hartley, F.R.S.; "On Charging Open-Hearth Furnaces by Machinery," by Jeremiah Head; "On the 'Weardale' Reheating Furnace," by H. W. Hollis; "On the Effect of Phosphorus on Cold Shortness," by Baron Hanns Juptner von Jonstorff; "On the Determination of Hardening and Carbide Carbon," by Baron Hanns Juptner von Jonstorff; "On Malleable Cast Iron," by G. P. Royston; "On Carbon Changes connected with Malleable Cast Iron," by G. P. Royston; "On Microscope Accessories for Metallographers," by J. E. Stead, Member of Council; "On Central Blast Cupolas," by T. D. West.

Of these six were read and four discussed. Six papers were taken as read, and not discussed. The latter consisted of the papers of Messrs. Carulla, Hartley, Stead, and West, and the two papers of Baron Juptner von Jonstorff. Mr. Royston's papers were those read and not discussed.

The formal proceedings having been got through, and the report of the Council having been read, the past-President, Sir David Dale, introduced the new President, Mr. E. P. Martin, who, as is well known, is the manager of the Dowlais Iron Company of South Wales. Sir Frederick Abel was next presented with a Bessemer medal; and then the President proceeded to read his inaugural address. This was of an eminently practical nature, and gave a most interesting description of the growth of the iron and steel industry at Dowlais almost from the earliest times, these historic works having been established for over a hundred years. It is interesting to notice that in the year 1791 the quantity of coal consumed in making a ton of iron in

the South Wales district was no less than 8 tons 1 hundredweight; while the average make of pig iron per furnace per week was 20 tons. Last year the maximum output of blast furnaces at Dowlais was 1600 tons per week, the consumption of fuel (coke) being equal to about 1½ tons of coal per ton of pig. The description of the manner in which the steel industry was introduced at Dowlais and its subsequent increase was commented upon by the President; one of the first works to take up the Bessemer process being the Dowlais Ironworks. Sir Henry Bessemer himself has stated that the first ingots were made from grey Blaenavon, which was converted into soft iron or steel without spiegel or manganese, the converter being lined with Stourbridge bricks. Menelaus, Edward Williams, and Edward Riley made successful tests at Dowlais immediately after Bessemer read his historic paper at the Cheltenham meeting of the British Association; the latter only of the three gentlemen named survives, he being present at the meeting and taking part in the discussion. When Mr. Bessemer came to Dowlais to continue the experiments a convenient refinery happened to exist opposite the furnace making cinder pig, and the iron from this furnace was by a singular and most unfortunate mischance employed for Mr. Bessemer's trials. The result, naturally, was very disappointing; and it is characteristic of the troubles inventors have to meet, that it was then contended such accidents were inherent to the process. Mr. Martin states that some time ago he came across one of these Bessemer ingots, which he analysed. As might be imagined, the phosphorus was extremely high—in fact, ridiculously so, being nearly 2 per cent. Unfortunately, the mistake in regard to the pig iron was not ascertained until some time after, so that, though the Dowlais Iron Company was one of the first to take up a licence to make Bessemer steel, they did not begin to roll steel rails till 1864. It will surprise a good many people to learn that large quantities of iron rails were rolled at Dowlais as late as the year 1882. The substitution of Bessemer and Siemens steel for wrought iron has reduced the number of puddling furnaces at Dowlais from 255 to 15.

The statistical part of the address was extremely interesting, especially that relating to American competition. American iron and steel makers exceed those of this country enormously by the output they obtain from their appliances. The Carnegie Steel Works have, the President stated, again surprised the world by the tremendous strides they have made. The Duquesne furnaces hold the world's record. Their best month's work has been 17,182 tons, or 572 tons per day, the actual best day's output being 690 tons, with a consumption of coke, as an average of a month, of 1700 lbs. per ton of pig iron. That is with a 57 to 60 per cent. ore, but in our country with a 48 to 50 per cent. ore we look on a make of a little over 1600 tons per week with satisfaction. "When this is compared with the gigantic outputs obtained from the Duquesne furnaces," the President said, "during the same period, it must be admitted that the results achieved here leave much to be desired." It may be added that still larger furnaces are being erected in America, and it is confidently expected that these will produce 1000 tons of pig iron per furnace per day. The Bessemer Steel Works at Duquesne are on the same huge scale as the blast furnaces, and other American works mentioned by the President are on a similarly imposing plan. In spite of the high wages paid in America, it has been possible by working in this wholesale manner to bring the cost of production to a very low ebb, until, as has been recently stated, it is a question now not how much steel we should send to America, but how far we can meet American competition within our own boundaries. The details as to freights, iron ore supply, by-products, wages and labour cost, railway rates, and other matters of a like nature were also discussed in the address.

Mr. Hollis' contribution was the first paper to be read. The Weardale furnace is of the re-heating type—that is to say, it is used for heating slabs, &c. It would be difficult to give a description of the design without the drawings by which the paper was accompanied. The author's object was to obtain continuous working without reversing, and yet to dispense with the regenerating chambers altogether, on account of their cost. It was also a point kept in view to introduce the flame in such a way as to obtain equal heating over the whole floor of the heating chamber. The broad principle upon which these ends was effected was by constructing the furnace so that the gas-flame would be introduced through, and surrounded by, a stratum of highly-heated air in the roof of the furnace. The flame would pour down on the slabs or piles to be heated, and would pass along the floor of the working chamber to an outlet port at each end. Judging by the details given by the author in his paper, and from the testimony of many competent judges during the discussion, the Weardale furnace seems to give satisfactory results.

The next paper read was the contribution of Messrs. Arnold and Knowles. The authors stated that in passing pure carbonic oxide over white-hot aluminium the metal became coated with a grey mixture of aluminal and carbon. Also, on blowing forty gallons of carbonic oxide through molten mild steel, containing about 4 per cent. of aluminium, the percentage of carbon was raised; this power of aluminium, to reduce carbonic oxides at high temperatures, has since been used to measure the permeability to furnace gases of clay steel melting crucibles. The experiments were carried out by melting ingots of Swedish iron, containing 99·85 of iron, with calculated quantities of aluminium. The ingots were broken up and re-melted, and it was found that in each case the greater part of the aluminium had been oxidised, and that the carbon liberated had converted the iron into hard steel; in one case remarkably high in silicon, doubtless reduced from the clay of the crucible during the prolonged time the steel was maintained in a molten state. The most important practical feature of the experiment was the fact shown that the walls of a crucible form little protection against the absorption of sulphur by the metal inside it. A good discussion took place on the reading of this paper, it being opened by Prof. Roberts-Austen, who gave what was a valuable supplement to the paper, consisting of details of work of a similar nature carried out by previous investigators. This question of the porosity of crucibles was, Prof. Roberts-Austen said, the dominant problem in the minds of metallurgists early in the century. The reading and discussion of these two papers, and of the President's address, occupied the first sitting of the meeting.

The first paper taken on the Wednesday was that of Mr. Jeremiah Head, in which he described an apparatus worked by electrical power, which has been introduced in America for charging Siemens furnaces. In this country hand labour is universally adopted for the purpose, although mechanical means are about to be introduced in some works. It is by such appliances as those described by Mr. Head that the American steel-makers are enabled to obtain the enormous output to which reference has already been made. It would be difficult to describe the machine without the diagrams which Mr. Head had shown upon the wall, or the very beautiful working model which Mr. Archibald Head exhibited at the conclusion of the reading of the paper. It must suffice to say that a powerful frame or gantry is run up in front of the furnace; by means of an electric motor a massive arm is projected from this. The arm is provided with what might aptly be called a hand, which grasps the boxes containing the furnace materials entirely by automatic means. The furnace door is then opened and the arm carries the iron box, with its charge of pig iron, ore or scrap, into the furnace; by another electric motor the arm is rotated, depositing the materials into the glowing bath of the furnace. The box is then withdrawn by the arm, the operation being continued until the whole charge is in position on the hearth; the apparatus is then moved on to the next furnace. The speakers during the discussion who had seen the apparatus at work gave testimony as to its efficiency.

The last paper read and discussed at the meeting was that of Mr. Bertrand. The combined process, to which reference is made in the title, consists of two open-hearth furnaces. The operations are divided into two stages, the metal being run, when half-treated, through a header from the primary to the secondary furnace, the latter being of the nature of a finery furnace. The perfect elimination of the phosphorus is not intended in the upper furnace, and therefore less lime may be added than would be otherwise necessary, and the quantity of slag to be melted is materially diminished. The plan of working adopted consisted in charging nearly all the siliceous and phosphoric pig iron into the primary furnace, and nearly all the scrap into the finishing furnace, adding in each such quantities of ore, lime, &c., as they were demanded. The advantage claimed is an increased output and a material reduction in the consumption of lime and basic material for lining the furnace hearths; a saving of fuel also takes place, it is thought. A long discussion followed on the reading of this paper.

The summer meeting this year will be held at Cardiff.

The annual dinner of the Institute was held on Tuesday,

May 11, at the Hotel Cecil, the President occupying the chair. Among those present were the Duke of Teck, Sir Bernhard Samuelson (past President), Sir David Dale (past President), Sir Lowthian Bell, Sir Courtenay Boyle, Sir Andrew Noble, Sir Henry Mance, Prof. Dewar, F.R.S., Prof. Ayrton, F.R.S., Dr. Ludwig Mond, F.R.S., Mr. Norman Lockyer, C.B., F.R.S., and Mr. B. H. Brough (the Secretary). After the loyal and patriotic toasts had been duly honoured, Prof. W. C. Roberts-Austen, C.B., F.R.S., proposed "Scientific and Professional Societies," which was acknowledged by Sir John Evans, F.R.S., and by Mr. J. Wolfe Barry, C.B., F.R.S. The toast of the evening, "Prosperity to the Iron and Steel Institute," was proposed by Sir Courtenay Boyle.

THE CULTURAL EVOLUTION OF "CYCLAMEN LATIFOLIUM."[1]

ON the occasion of the discussion on "Variation in Plants and Animals," which took place on February 25, 1895, it occurred to me that it might be useful to give an illustration of the amount of change which has been effected in a plant by continuous selection under cultivation in a comparatively short time. I, therefore, placed upon the table an example of the wild and of the cultivated form of the garden "cineraria" (*C. cruenta*).

The choice of this species was purely accidental. It was, however, violently impugned. It was contended that the garden cineraria was not the result of the development of a single species, but that it was of multiple origin, and the result of the intercrossing of several. It was further contended that its change from the wild form had not been gradual, but by discontinuous steps or "sports." Neither contention seemed to me well founded. But I admit that, owing to the lapse of time since the so-called "improvement" of the cineraria commenced, it is impossible to give formal proof that the process has been what I described. Mr. Darwin met with the same difficulty. He remarks: "We know hardly anything about the origin or history of any of our domestic breeds" ("Origin," 6th ed., p. 29) As is, however, well known, he regarded them as the result of accumulation by selection of successive slight variations. But he also tells us that "the chance will be infinitely small of any record having been preserved of such slow, varying, and insensible changes."

It seemed to me important, therefore, to obtain the history of some cultivated species which would not be open to the objections urged in the case of the cineraria.

After some consideration I selected the plant known in gardens as *Cyclamen persicum*. Owing to the kindness of the skilful horticulturists who have worked upon it, I am able to place on record a nearly complete history of the changes it has undergone.

The genus *Cyclamen* belongs to the small order *Primulaceæ*, which in its affinities is somewhat isolated. *Cyclamen* itself is distinguished from the rest of the tribe *Lysimachieæ*, to which it belongs, by the reflexed segments of the corolla.

Cyclamen persicum, Mill., is a name given by gardeners to a form slightly modified by cultivation of *C. latifolium*, Sibth., a species confined to Greece and Syria. There is a good figure of the type in Sibthorp's "Flora Græca" (t. 185). It has pink flowers, with a ring of darker colour at the throat. The species is said to have been first cultivated in Europe at Lille in 1731 ("La Semaine Horticole," 1897, p. 23), having been introduced from Persia. There must have been some error as to its origin, for Boissier points out that the species is not found in that country ("Flora Orientalis," vol. iv. p. 12). In all probability it was obtained from Syria. The Lille plant ultimately went to Ghent, and it has been asserted that all the cultivated forms in existence are descendants from this one individual. The assertion cannot be proved, but is not improbable. It is known to have been a variety with white flowers. As will be shown, the forms now in cultivation have been derived from a white-flowered one, which in turn might well have been derived from the Lille plant.

Such a modified form was, in fact, that described by Miller, in 1768, in the eighth edition of his "Gardener's Dictionary," under the name of *Cyclamen persicum*. He describes the flowers as "pure white with a bright purple bottom." It was figured in the *Botanical Magazine* in 1787 (t. 44), and it has come down little altered to our own day. In 1875 Boissier describes it as "forma hortensis a me nunquam spontanea visa." It still exists in cultivation, and is the (old) "crimson and white" of Messrs. Sutton. It seems always to have been popular in cultivation on account of its agreeable fragrance. This confirms the Syrian origin of the original stock, for a white-flowered form "is found in Palestine which is very fragrant" (*Roy. Hort. Soc. Journ.*, N. S., vol. xiii. p. 163).

Early in the century some colour variations were in cultivation. Several as well as the typical *C. persicum* were figured in the "Flore des Serres" in 1877 (t. 2345). These record the amount of change from the wild type which had been accomplished in a century and a half. One striking seminal sport (*C. persicum*, var. *laciniatum*) is figured in the *Botanical Register* in 1827 (t. 1095). It is remarkable for spreading corolla-segments broader than usual, and cut at the edges. It does not appear to have been perpetuated, but in some degree it anticipated some of the remarkable modern developments.

I am informed by Mr. James Martin, the accomplished propagator of Messrs. Sutton, that the recent remarkable development of the cyclamen began about 1860, and, at any rate in their hands, started with the old "crimson and white." It will be seen from the accompanying figures how little this differs from the wild type. Fig. 1 represents a flower of the latter from a plant imported by Messrs. Sutton from Syria after six years of cultivation. It is not appreciably altered. Fig. 2 represents a flower of their "crimson and white"; it only differs from the wild type in having shorter, broader, and less twisted corolla segments.

In considering the progress which has been made since 1860 under the skilful hands of Mr. Martin and others, it is important

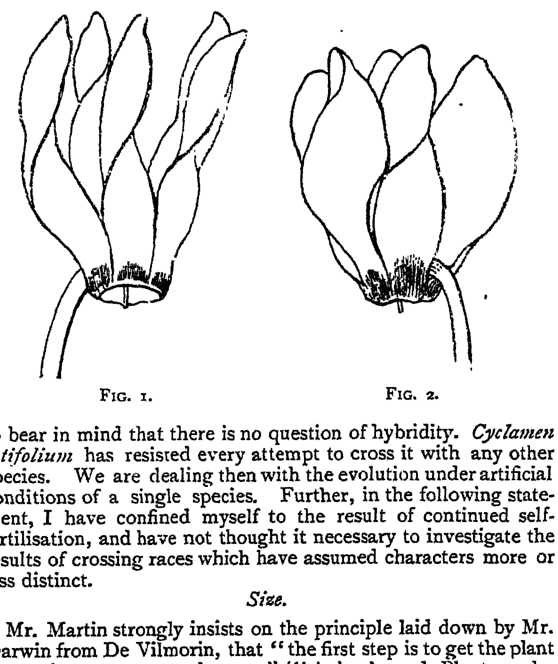

FIG. 1. FIG. 2.

to bear in mind that there is no question of hybridity. *Cyclamen latifolium* has resisted every attempt to cross it with any other species. We are dealing then with the evolution under artificial conditions of a single species. Further, in the following statement, I have confined myself to the result of continued self-fertilisation, and have not thought it necessary to investigate the results of crossing races which have assumed characters more or less distinct.

Size.

Mr. Martin strongly insists on the principle laid down by Mr. Darwin from De Vilmorin, that "the first step is to get the plant to vary in any manner whatever" ("Animals and Plants under Domestication," vol. ii. p. 262). As Mr. Martin puts it, "the breeder must work with nature." It is his practice to seize the smallest deviation, even so small an indication as the slightest difference in a cotyledon of a germinating seed. The first direction of work would, however, for commercial purposes, be to develop the size of the corolla. Figs. 3 and 4 show two stages which have been reached by progressive selection from "crimson and white." Messrs. Sutton have sent me photographs of the largest flowers hitherto produced by them. Fig. 5 is copied from one of these. The vertical depth is 3 inches. This is more than double that of the form with which they started; the increase in breadth of the segments is at least six times. This represents the continuous work of forty years. As the work was not done for a scientific purpose, the whole of the progressive steps have not been preserved or recorded. Only saleable stages have survived. But Mr. Martin emphatically denies that they have been attained by other than progressive selection, or

[1] "The Cultural Evolution of *Cyclamen latifolium* (Sibth.)." By W. T. Thiselton Dyer, C.M.G., C.I.E., F.R.S. Received and read at the Royal Society, March 18.

that they have been reached by leaps and bounds. In developing any particular character it is, to use his own words, always done by a "ladder," *i.e.* continuous self-fertilisation and selection. The stage shown in Fig. 3 owes its preservation to its having retained fragrance. Beyond this stage fragrance has been lost.

An interesting question is whether there is any limit to the extent to which an organ can be developed, and if so, what? It is to be hoped that Mr. Martin will continue his

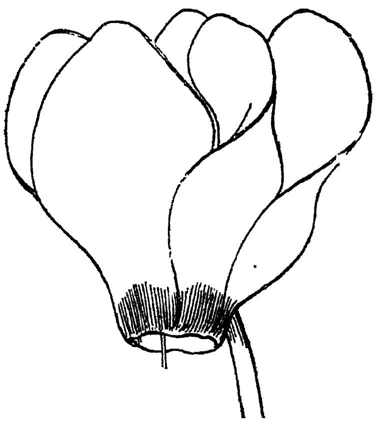

FIG. 3.

work in this direction and strive, if only as a matter of scientific interest, to increase the size of the corolla to the maximum possible. The only check will probably be found to be the general balance of nutrition.

Spreading.

I was much struck to find amongst a magnificent series of specimens, kindly sent me by Messrs. Sutton, forms with the segments of the corolla spreading instead of reflexed (Fig. 6).

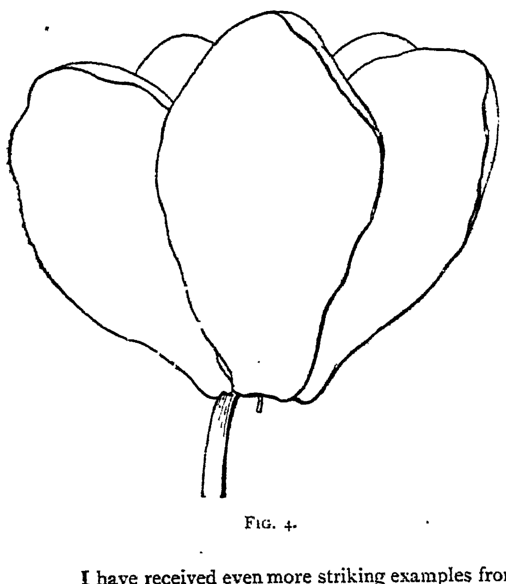

FIG. 4.

I have received even more striking examples from Messrs. Hugh Low and Co. This is remarkable because, as I have already pointed out, the latter is a distinctive generic character in *Cyclamen*. Although the alteration in the appearance of the flower is enormous, the structural change is slight. It is merely a matter of direction of growth. It amounts, however, to the loss of a generic character and a reversion to a more generalised type. The change is therefore essentially atavistic.

I was unable to obtain from Mr. Martin any explanation of how this particular variation had come about, but he informed me that it had been of frequent occurrence. Spreading flowers had always been destroyed as departing from a desirable type. More recently, on account of their orchid-like habit, they had taken the popular fancy, and had been preserved.

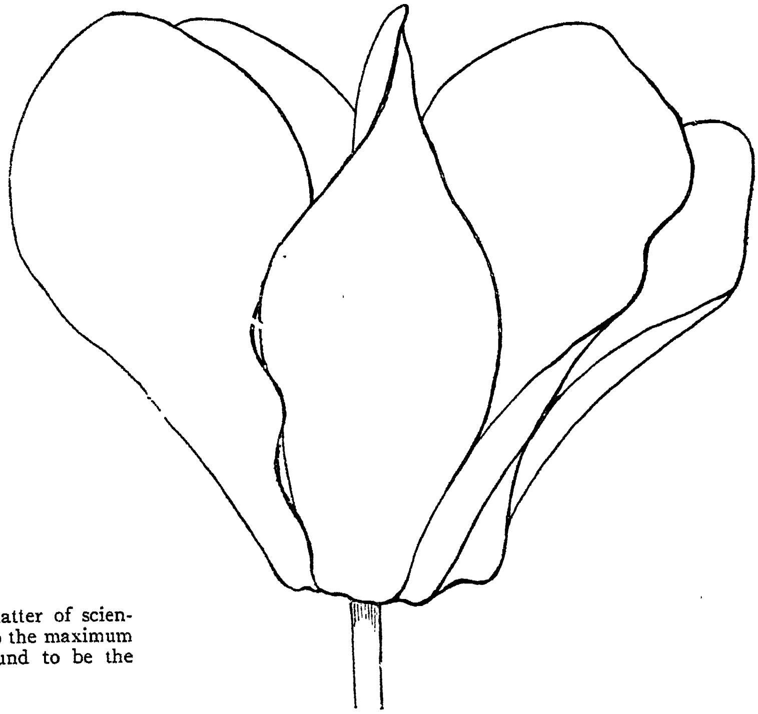

FIG. 5.

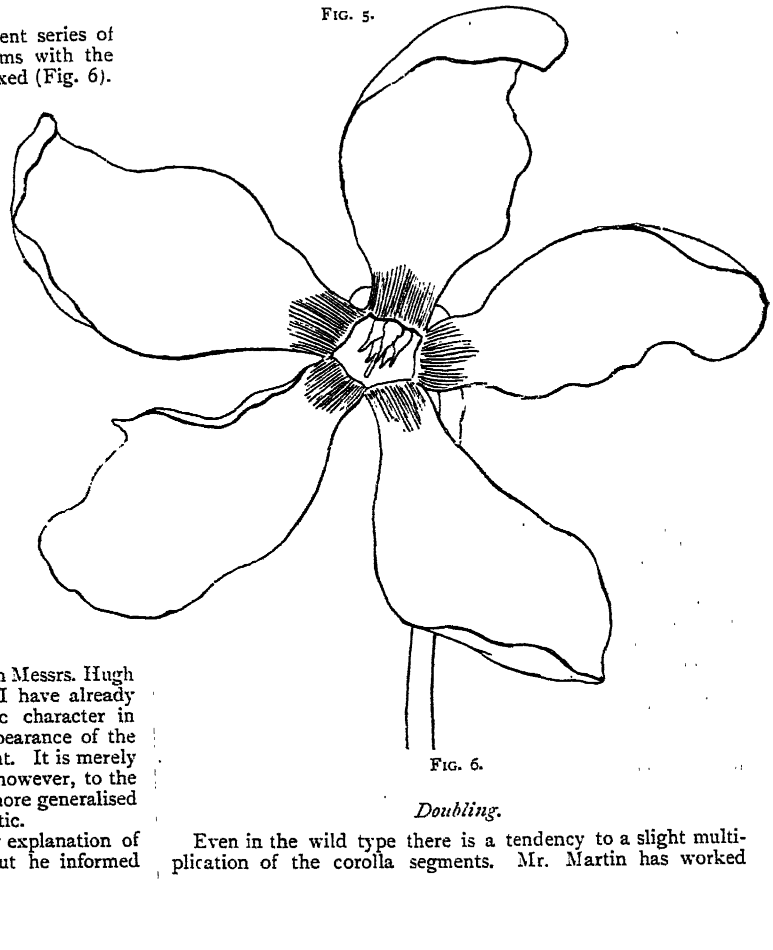

FIG. 6.

Doubling.

Even in the wild type there is a tendency to a slight multiplication of the corolla segments. Mr. Martin has worked

upon this, and has produced flowers such as shown in Fig. 7. He seems to think that there is no limit to which this multiplication cannot be carried practically, and hopes in time to produce "mop-headed" flowers like a chrysanthemum. The so-called doubling of flowers, as in the rose, is a teratological phenomenon, and is due to the conversion of stamens into petals. But in *Cyclamen* this is not the case. The stamens, which are normally equal in number to the corolla segments, are also multiplied. Although a quinary symmetry is general in the *Primulaceæ*, *Trientalis*, a near ally of *Cyclamen*, ordinarily exhibits a considerable range in the number of parts of the flower. Here again *Cyclamen*, under artificial conditions, shows a reversion to a more generalised type.

Colour.

There is evidence that seminal variation as regards colours occurred at least as early as 1820, but the modern forms with large coloured flowers, according to Mr. Martin, originated in a different way and can be traced back to the old crimson and white. That preserves the crimson ring round the throat, but is otherwise an albino. There is nothing remarkable in this. Any species in nature may produce white flowers; albinism is in effect the commonest of all variations. "Giant white" (Figs. 4 and 5) is a pure albino, in which the crimson ring has been suppressed.

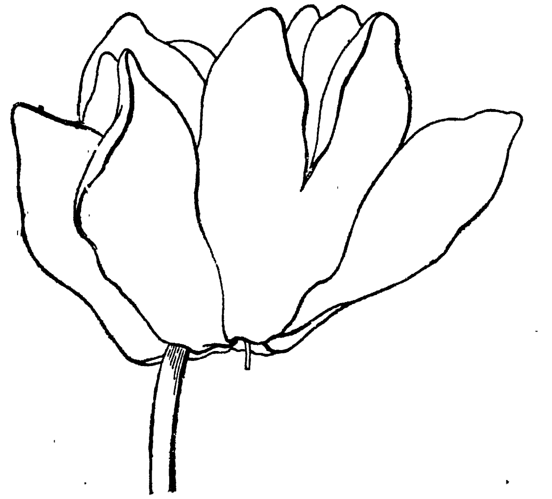

FIG. 7.

The modern coloured forms were obtained in the first instance by selecting forms in which the coloured ring showed a disposition to spread into the white corolla segments. The first indication would be a scarcely perceptible streak. By selection from self-fertilised plants the streak was widened into a stripe. Continuing the process, the stripes united, and a uniformly coloured flower was obtained.

The more striking colours, such as that of "Vulcan," which is a dark crimson, were, however, obtained not by progressive selection, but amongst the progeny of cross-fertilised plants.

I learn from Messrs. Hugh Low and Co. that coloured varieties, of course when self-fertilised, come true from seed. This is in accordance with a well-known principle (Darwin, "Cross and Self-fertilisation," p. 460).

The Butterfly Form.

This has been obtained independently by several horticulturists. The segments are partially spreading, and concave on their inner surface. One of the most remarkable is that raised by M. de Langhe-Vervaene; it is represented in Figs. 8 and 9. He informs me that "these are the products of the eleventh year of improvement." He adds: "I never crossed them with any other strain; I do not like crossing races; I prefer improving them." He has kindly favoured me with the following detailed account of the mode in which the strain has been developed and improved. I quote it in his own words:—

"Les Cyclamen Papilio que j'ai obtenus sont issus directement des *Cyclamen persicum*, var. *giganteum*.

"Il y a environ une douzaine d'années je remarquais parmi mes semis de Cyclamen une plante qui attira mon attention par l'extrême beauté de son feuillage dentelé et marbré. En examinant la plante, je vis qu'elle portait une grande quantité de boutons; ceux-ci étaient de forme plus arrondie et plus courte que ne le sont généralement ceux des *Cyclamen persicum*. La plante fut mise à part; quand elle commença à fleurir, elle m'étonna par la forme bizarre de ses fleurs. Ces diverses circonstances m'engagèrent à en recolter les graines.

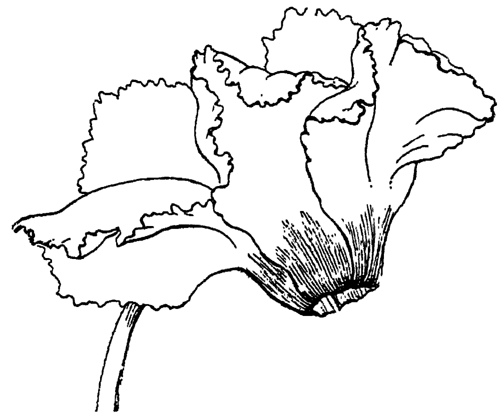

FIG. 8.

"L'année suivante j'obtins quelques jeunes plantes. Au moment de leur floraison, elles purent être comparées à la plante mère.

"Les plus parfaites de ces plantes furent choisies pour servir de porte-graine, et leurs fleurs furent fécondées entre elles. L'année suivante je fus assez heureux pour constater un nouveau progrès; mes gains surpassaient leurs parents que j'avais conservés. On pouvait apercevoir, dans ces semis aux caractères persistants, le point de départ d'une race nouvelle.

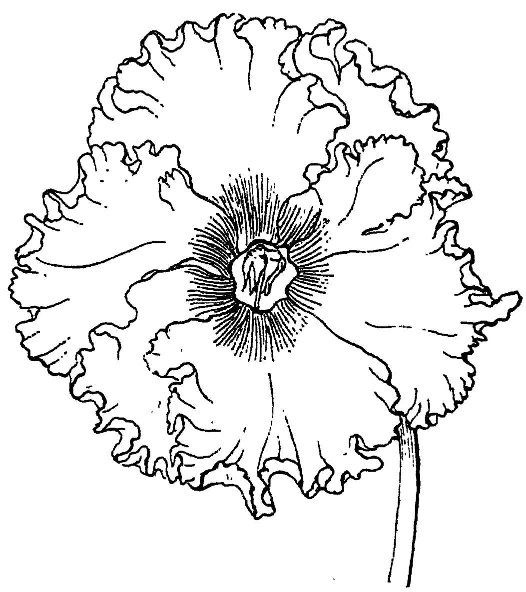

FIG. 9.

"Je continuai dans cette voie; au bout de quatre ans, j'étais en possession de quelques sujets fort remarqués. Les pétales des fleurs étaient amples et plus longs; ils se redressaient comme les ailes d'un papillon qui s'apprête à prendre son vol.

"La race se caractérisa chaque année davantage.

"Encouragé par le résultat déjà obtenu, je m'occupai à rechercher la diversité des coloris. Après quatre années je ne

possédais dans mes semis que des plantes à fleurs rouges ; j'avais en triant les sujets pour la reproduction toujours écarté les fleurs les moins brillantes. Il s'agissait maintenant d'obtenir des fleurs à couleurs pâles. Des efforts nouveaux furent fait dans cette voie ; je vis au bout de deux ans après apparaître la première fleur aux pétales blancs et à onglet rouge ; dès lors les croisements se multiplièrent au point qu'après la neuvième année la perfection des formes et des coloris est telle que tous ceux qui voient mes Cyclamen Papilio sont unanimes à reconnaître leur mérite et leur perfection des fleurs."

In this case the basis of the new strain was found in a marked variation or "sport." The deviation from the type could not, however, have been very marked. The most remarkable feature in "Papilio" as now developed is the curled and toothed margin of the corolla segments. These peculiarities repeat characters which occur elsewhere in the order. In *Soldanella* the toothing is conspicuous: curling occurs in cultivated varieties of *Primula sinensis*. It is interesting to observe in "Papilio" that in the primary variation there was a correlation between the toothing of the corolla segments and of the leaves.

Cresting.

The most remarkable form which has made its appearance under cultivation is that in which a plumose crest has developed on the inner surface of each corolla segment. This is shown in Fig. 10, which represents the "Bush Hill Pioneer," raised by Messrs. Hugh Low and Co. I quote the account of its development with which they have been so good as to furnish me:—

FIG. 10.

"This interesting variety was first observed in our nurseries some four years since, but how it originated we are unable to say.

"At that time, the only peculiarity about the variety was a *very slightly raised rib* running part of the way up the petals, and showing *no tendency to branch*. This was, however, considered sufficiently curious to follow up, and we seeded it with its own pollen.

"The young plants from this *showed a decided improvement*, the rib in some cases *showing a marked tendency to branch*. The best varieties (ten in number) were again fertilised with their own pollen, and the plants now being exhibited by us have resulted, although, needless to say, they are among the finest obtained up to the present, though *all* show a further improvement, *every flower* having a well-branched feather on the petals.

"We have this year found some colour in one plant, and we believe we shall have no trouble in obtaining crested flowers in a variety of colours."

The corolla segments of *Cyclamen* have no mid-rib. The appearance of such a structure is a reversion to the original leaf-type. The development of a crest from a mid-rib carries reversion very far back indeed. The branching of a leaf-structure in the plane in which it is expanded is common enough; branching in a plane at right angles to this is rare. Leafy outgrowths frequently occur from the mid rib in the cabbage (Masters' "Teratology," p. 455). In this case the structure of the leaf approximates to that of a stem, of which, indeed, the leaf may be regarded as a modification.

An interesting fact with regard to this singular variation is that it has appeared more than once, and independently. It first occurred in 1885, but seems afterwards to have been lost sight of (*Gardener's Chronicle*, 1885, p. 536). It has also occurred in a red-flowered form in France (*Revue Horticole*, 1897, pp. 98 and 130), in which case it was also perpetuated by seed.

I have not succeeded in discovering any similar structure in any primulaceous plant occurring in a wild state. Dr. Masters, however, informs me that it has been observed in cultivated forms of *Primula sinensis*. The tendency thus seems to be latent in the order, though why it should be so I am unable to explain.

Some theoretical interest appears to me to attach to the rapid development of so striking an ornament of a corolla segment. Such appendages are frequent enough in orchids, and are regarded as adaptations to cross-fertilisation by insects. Their gradual evolution might be thought to require a long period of time; but in the present case we have definite evidence that such a structure may be developed by selection with great rapidity.

Conclusion.

(1) The facts which I have stated appear to me to establish the result that, when once specific stability[1] has been broken down in a plant, morphological changes of great variety and magnitude can be brought about in a comparatively short space of time. This appears to me to have a very important bearing on the rate of evolution. Mr. Darwin quotes Lord Kelvin as insisting "that the world at a very early period was subjected to more rapid and violent changes in its physical condition than those now occurring"; and he adds, "Such changes would have tended to induce changes at a corresponding rate in the organisms which then existed" ("Origin," sixth ed., p. 286). That changes may be effected with considerable rapidity cannot, I think, be denied.

(2) It is further, I think, abundantly proved in the present case that, though sudden variations do occur, they are, as far as we know, slight as long as self-fertilisation is adhered to. The striking results obtained by cultivators have been due to the patient accumulation by selection of gradual but continuous variation in any desired direction.

(3) The size which any variable organ can reach does not appear to be governed by any principle of correlation. Large flowers are not necessarily accompanied by large leaves. Under natural conditions size is controlled by mechanical limitations and by the principle of economy. Nature cannot afford to indulge in anything unnecessary for the purpose in view (see Darwin, "Origin," 6th ed., p. 117).

(4) The general tendency of a plant varying freely under artificial conditions seems to be atavistic, *i.e.* to shed adaptive modifications which have ceased to be useful, and either to revert to a more generalised type or to reproduce "characters which are already present in other members of the same group" (see Darwin, "Origin," 6th ed., p. 127). This conclusion must, however, be accepted with caution, for we must remember that in a case like the present we are only acquainted with variations which have been preserved with a particular end in view.

(5) The case of "cresting" shows that the plant still possesses the power to strike out a new line and to develop characters which would even be regarded as having specific value, as in the total change which has been effected in the form of the leaf in *Primula sinensis*. If such a race developed any degree of sterility with other races, it would have satisfied Huxley's criterion for the artificial production of a new species.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The Savilian Professorship of Geometry being vacant by the death of the late Prof. Sylvester, the Electors will proceed to the appointment of a successor in the course of the present Term. The duties of the Professor are defined in the following provisions of the Statutes:—"The Savilian

[1] For a general discussion of the principles of variation and specific stability, see NATURE, vol. li. pp. 459-461.

Professor of Geometry shall lecture and give instruction in pure and analytical geometry. The Professor shall reside within the University during six months, at least, in each academical year, between the first day of September and the ensuing first day of July. He shall give not less than forty-two lectures in the course of the academical year; six at least of such lectures shall be given in each of the three University Terms, and in two at least of the University Terms he shall lecture during seven weeks not less than twice a week." The emoluments of the Professorship as determined by Statute are as follows:—"He shall be entitled to the emoluments now assigned to the Professorship and derived from the benefaction of Sir Henry Savile, Knight, or from the University Chest; and shall receive in addition the emoluments appropriated to the Professorship by the Statutes of New College." The total amount of these emoluments is 900*l.* a year, and cannot exceed that amount. Applications, together with such papers as a candidate may desire to submit to the Electors, must be sent to the Registrar of the University, Clarendon Building, Oxford, on or *before* June 12, 1897.

All examinations within the University will be suspended on June 22.

Prof. Gotch, F.R.S., has been elected a Delegate for the extension of teaching beyond the limits of the University.

Mr. W. Garstang, Fellow of Lincoln College, will give a public lecture in the hall of Lincoln College on May 25, on "Recent Researches in Marine Biology."

The Botanical Museum of the Department of Botany has been undergoing rearrangement under the supervision of Mr. Church. The work is now nearly completed. Some 4000 new specimens have been added to the Herbarium during the past year.

The Curators of the Botanic Garden have presented their ninth Annual Report to Convocation. It is satisfactory to note that the deficit of last year has been considerably reduced, and a great number of exchanges with other Gardens have been made.

At a meeting of the Junior Scientific Club, held on Friday, May 14, papers were read by Messrs. E. S. Goodrich and E. F. Morris. A proposal to amalgamate with the Ashmolean Society fell through, the Club not being in a condition to bear the somewhat heavy financial burden which would be consequent on amalgamation.

An examination for the Shute Scholarship in Animal Morphology (a Non-Collegiate scholarship) is announced. It will take place in July 1897, the scholarship being of the annual value of 50*l.* Candidates must be in need of assistance at the University. The scholarship is open to all, without limit of age, with the exception of members of the University of more than eight terms' standing. Names are to be sent to the Censor of Non-Collegiate Students, High Street, Oxford, on or before Monday, June 14.

CAMBRIDGE.—The Committee for promoting the admission of women to titular degrees appears to be disintegrating. On May 17 a fly-sheet was circulated by the President of Queens' (Dr. Ryle), the Registrary (Mr. J. W. Clark), Mr. E. S. Roberts (tutor of Caius), and Mr. W. L. Mollison (tutor of Clare), expressing their decision to withdraw their support from the proposals before the Senate. They are now convinced the removal of the alleged grievance, felt by a comparatively small number of women, would be bought at too high a price, when considerably more than half of the resident members of the Senate are bitterly opposed to the measure, and would view it, if carried, as a grave betrayal of trust. They express the opinion that a victory under such conditions would be worse than a defeat, and that the passing of the Graces would prove injurious to the best interests of the University. They hope that before long a solution will be found in which the Universities of Oxford and Cambridge may act together. There is good reason to believe that the views which these influential members of the Senate have had the courage publicly to express, are shared by others who are still, nominally, on the side of the women, and that these will now either abstain from voting, or follow the lead now given to them by giving their voice against the much-discussed resolutions. The result will be declared soon after 3 p.m. on Friday afternoon, and, in the interests of peace, it is hoped that the majority will be decisive. A narrow victory for either side would settle nothing. A London Committee of about one hundred members has been formed to secure the rejection of the Graces, and is actively engaged in disseminating information and securing promises to vote *non-placet.* Lord Kelvin is chairman, and Dr. E. Freshfield secretary; among the other members are the Astronomer Royal, the Registrar of the Royal College of Physicians, Dr. Norman Moore, Lord Stanmore, and Sir Walter Besant.

Mr. W. N. Shaw, F.R.S., has been reappointed a University Lecturer in Experimental Physics.

Applications for leave to occupy the University Tables in the Zoological Stations at Naples and Plymouth are to be sent to Prof. Newton, F.R.S., Magdalene College, by May 26.

THE President of the Board of Agriculture has appointed a Departmental Committee to inquire into the working of the Universities and College Estates Acts, 1858 to 1880, and to report whether any, and, if so, what, amendments therein are desirable.

IT is perhaps worthy of notice that a new Board school, erected in Faraday Street, Walworth, at a cost of 15,000*l.*, has been named the Michael Faraday School, in honour of Faraday, who was born in the parish. May the children who receive instruction in the school strive to follow the example set them by the great investigator whose name the school bears.

THE International Submarine Telegraph Memorial Committee has granted "The Sir John Pender Gold Medal," value 5*l.* 5*s.*, to the Glasgow and West of Scotland Technical College. It is given annually to the best student who at the same time obtains the college diploma in electrical engineering. At the end of this session, which terminated last week, it was awarded to Mr. David Robertson.

Science announces the following gifts to educational institutions in America:—The will of the late John Foster, of Boston, gives 120,000 dols. to public purposes, including 10,000 dols. to the Massachusetts Institute of Technology; the will of the late Charles Bell, of Springfield, Mass., bequeaths 7000 dols. to Wellesley College for a scholarship fund; Brown University receives 10,000 dols. by the settlement of the will of the late Mrs. Maria L. Benedict, of Providence.

IN the House of Commons, on Monday, Mr. Brynmor Jones asked the First Lord of the Treasury whether it was the intention of the Government to reintroduce the University of London Bill this Session; and, if so, when. In reply to the question, Mr. Balfour said that the President of the Council hoped to introduce a Bill into the House of Lords shortly. There is some reason to expect that the difficulties, which prevented it from passing last year, will be removed, and certain negotiations are going on with that object.

THE following are among recent appointments:—Mr. C. H. Warren to be Instructor in Mineralogy in the Sheffield Scientific School of Yale University; Dr. Karl Paal to be Professor of Chemistry at Erlangen; Dr. Raphael Freiherr von Erlanger, privat-docent in Zoology at Heidelberg, to be Professor; Dr. F. Foerster, privat-docent in Chemistry at the Dresden Technical High School, to be Professor; Dr. Petzold, privat-docent in Practical Geometry at the Technical High School at Hanover, to be Professor; Dr. Anding, privat-docent in Astronomy at Munich, to be Observer on the International Commission for the Measurement of the Earth; Dr. J. Thomayer to be Professor of Pathology at the Bohemian University at Prague; Mr. J. F. Crawford to be Demonstrator in Experimental Psychology in Princeton University.

IN October last a Committee was appointed "to inquire into the mode in which the grants to Science and Art Schools are distributed, and to report whether any alteration should be made therein." The Report of this Committee has just been published as a Blue-book, in which is also included a revised edition of the Science and Art Directory, embodying the recommendations of the Committee. Some of the important changes advocated are as follows:—(1) "In counties and county boroughs in England possessing an organisation for the promotion of secondary education, the authority so constituted may notify its willingness to be responsible for the science and art instruction within its area." This recognition of local authorities as those who should be responsible for secondary instruction will, the Committee thinks, simplify the work of central administration, secure greater efficiency in the schools, and be a protection against this undue competition and multiplication.

(2) To encourage the study of languages and literary and economic subjects, and to meet the objection that the Science and Art grants tend to promote a one-sided education, it is proposed that any *bonâ fide* student attending an evening science or art class shall be able to earn a grant by attendance at University Extension courses of lectures. It is expected that the grants made on this account will only absorb an infinitesimal proportion of the total grants disbursed by the Department of Science and Art. (3) Hitherto certain restrictions as to income have existed which precluded some students from earning grants or winning scholarships. These are to be abolished; but, to prevent abuse, a regulation has been added that schools in receipt of payment must be "approved by the Department as suitable in character and financial position to receive aid from public funds," and with reference to persons eligible to hold certain scholarships and exhibitions, a provision has been added that "the Department may refuse to fill them with persons whose circumstances do not appear to warrant such aid." (4) It is suggested that the Honours examination in each subject should be divided into two parts, one less advanced in character than the other.

LORD HERSCHELL, the Chancellor of the University of London, took the opportunity of referring to the need of a teaching University, at the meeting held on Wednesday in last week for the distribution of medals and certificates. A University was not worthy of the name, he is reported by the *Times* to have said, unless it inspired a love of knowledge for its own sake. It was this conception of the mission of a University which made him desire to introduce a different element into their University, so that it should no longer be the main object of its members to obtain degrees; and if, even as regarded a minority of students, the function of teaching were added to that of examining, the idea of a University would be realised in a far higher degree than it was at present. The question of a change in their constitution had been before the country for many years, and he would not approach it in a controversial spirit, but he could not but express a hope that some step would soon be taken. The discussions of the last two years had removed many misconceptions between those who held widely different views from each other; and the progress of consideration and the interchange of views might, he thought, lead to approximation between those who appeared to stand asunder. But he was inclined to think that the questions at issue might better be solved by an independent body than by mutual concessions on the part of opposing parties. The danger of compromise was that each side might concede something which ought not to be conceded—a danger which an independent body might avoid. The main objection urged against change was that it might tend to lower the quality of degrees. If that were likely to be the result, he should be the enemy of change; but he did not believe it passed the wit of man to devise means whereby the University should become a teaching body and yet both maintain its present high standard and safeguard the interests of external students. Certainly those members of the Senate who were favourable to change were the last men who would wish to lower the degree standard. But he wished to point to a real danger. There could be nothing more fatal to the prestige and influence of their University than that there should arise by its side another University in London which should teach as well as examine; and if the choice lay between such a second University and the modification of the existing University of London, surely the latter alternative was preferable. The feeling in favour of a teaching University was so strong that in one form or another it must succeed in its aim, and surely it was wiser to look facts in the face than blindly to oppose the inevitable march of events.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, May 14.—Mr. Shelford Bidwell, President, in the chair.—Mr. W. Watson described an instrument for comparing thermometers with a standard. The thermometers to be compared are inserted together in an enclosed vapour-tube, the temperature of which can be maintained very constant at different parts of the scale. The apparatus is an adaptation of the arrangement designed by Ramsay and Young for vapour densities. It consists of a wide vertical glass tube, with a narrower tube attached at the top. The narrow tube bends downwards, and communicates with a closed vessel of considerable volume. A portion of the vertical tube is surrounded by a condensing-jacket, and a manometer-tube is inserted near the top. The object of the large vessel is to diminish errors arising from fortuitous changes of pressure, resulting from small leakages or "bumping" of the boiling liquid. Electrical heating of the bulb containing the liquid, effectually removes the "bumping." The following liquids, used consecutively, give a range of temperature from 20° C. to 120° C.: carbon bisulphide (20° to 46°), ethyl alcohol (80°), chlorobenzine (120°). The apparatus when once started required very little attention; from results submitted by the author, the variations do not exceed 0·02° C. per hour. In constructing the various parts, the difficulties of glass-blowing are reduced by making the joints of india-rubber stoppers, attached to the glass with india-rubber solution. Each joint is jacketed with glycerine. If the above liquids are used in the vaporiser, the scales of the thermometer can always be read within the tube; it is only with water that the condensed vapour gives trouble. Prof. Ayrton thought the apparatus would come into extensive use; it did away with errors arising from differences of length of thermometer stems; it left no question as to the equality of temperature of the two bulbs; and there was no probability of error due to a difference of thermal "lag" in any two thermometers. Mr. Watson, in replying to a question of Prof. Perry's, said the fact of using india-rubber joints limited the available range of temperature. Working with blown joints, Ramsay and Young had found no difficulty with their vapour-density experiments at higher temperatures.—Prof. Carey Foster read a paper, by Mr. D. K. Morris, of Zürich, on the effect of temperature upon the magnetic and electric properties of iron. The investigation relates to the measurement of the magnetic permeability, hysteresis, and electrical resistance of iron, simultaneously, at different temperatures. The specimens are formed into annular rings, made from iron strip. The strip is first lapped round with asbestos paper and mica, and then wound upon itself to the required thickness. A platinum wire is included in the mica lappings, for thermometrical purposes. Upon each annular ring are the following windings: (1) a primary magnetising coil; (2) a secondary coil connected to a ballistic galvanometer; (3) an electrical heating coil. Further, the iron strip is itself connected to a Wheatstone's bridge, for resistance measurements. The coil can be heated to 1050° C. At the higher temperatures, the surrounding air has to be freed from oxygen; this is done by enclosing the coil in a suitable vessel, and exhausting with an air-pump. When most of the air has thus been removed, the residual oxygen is absorbed by an electrically-heated iron wire. Curves are drawn representing the changes of permeability at the different temperatures; and, at the same temperatures, the corresponding hysteresis loops are plotted. The hysteresis diminishes with temperature; it nearly vanishes at about 764° C. At the suggestion of Prof. Ayrton, it was agreed that the discussion on this paper should be adjourned until the publication of the results. The paper will, therefore, be printed without delay.—Mr. Rollo Appleyard read a paper on the formation of mercury films by an electrical process. If a sheet of damp leather, or similar permeable substance, is used as a separating diaphragm between two bodies of mercury, and a current is sent through it, a film of mercury is deposited upon the surface connected to the positive pole; and the film remains on the diaphragm after removal from the apparatus. If the diaphragm is replaced in the apparatus, and subjected to a current in the reverse direction, the film vanishes from that surface, and a second film appears on the other side; that is to say, the film is always on the side of the diaphragm connected to the positive pole of the battery, and there is no film on the negative surface. Different diaphragms and films were exhibited on filter-paper, asbestos-paper, plaster of Paris, &c. A current of about one-fiftieth of an ampère, or more, is necessary. A sheet of tinfoil included between folds of filter-paper becomes perforated with pin-holes when the current is passed between the outside surfaces. This happens whether the outside electrodes are mercury or metal plates. If the top electrode should be tinfoil, this also becomes perforated as well as the included sheet. A further experiment was shown in which a gold coin is placed upon the folds of filter-paper; the current produces a gold-discoloration which penetrates the folds. This, it was suggested by the author, may help to account for the formation of metallic lodes and veins as they exist in rocks;

and they may partly explain the "inductoscripts" of Mr. F. J. Smith. Dr. S. P. Thompson said he did not know of any other example of an *anode* being more active, mechanically, than the *kathode*, except the electric arc. He was surprised that the film should appear on the positive surface. Mr. Shelford Bidwell thought selenium presented, in some of its actions, an example of the *anode* being thus active. Prof. Ayrton said that if a vessel containing a substratum of mercury amalgam was filled up with water in which gold crushings were washed, the gold descended into the amalgam. This, however, might be due partly to gravity, and partly to simple electrolysis. Mr. Appleyard said he had no definite views as to the formation of the films. He believed it to be a secondary effect of electrolysis, aided by electric osmosis. The experiments of Mr. C. K. Falkenstein upon the electric tanning of leather, and the early results of M. Perret, helped the idea of electric osmosis; they were not sufficient, however, to justify that theory without further research. A careful chemical analysis of the deposits left in the folds of filter-paper would be the best guide.

EDINBURGH.

Royal Society, May 3.—Prof. Chrystal in the chair—A paper on Dschâbir Ben Hayyân and the chemical writings ascribed to him, by Prof. Ferguson.—The seasonal changes in the pressure and temperature of the atmosphere from May to June, and November to December, by Dr. Buchan.—Dr. W. W. J. Nicol read a paper on supersaturation. After a short reference to his previous papers on supersaturation, in which the author showed that supersaturated solutions differ in none of their properties from ordinary solutions, if only the temperature be not allowed to fall below a certain point (depending upon the nature of the salt in question, and the concentration of the solution), and contact with the solid salt or with an isomorphous salt be carefully prevented, he repeated his statement that there is really no such thing as a supersaturated solution, that such solutions are in reality saturated or non-saturated solutions of what may be termed the anhydrous salt; that is to say, they contain the salt to which the *whole* of the water is similarly related, no distinction existing in solution between the water organically present as water of crystallisation, and the solvent water. The author proceeded to explain that he was forced into premature publication of his recent work on the subject, by the appearance of a paper by Ostwald in the last number of the *Zeitschrift für Physikalische Chemie* (see pp. 61-2.) In this paper, Ostwald was apparently on the verge of coming to the same conclusions as those at which the author had arrived as the result of his more recent work, thus no other course was open to him than the publication of the work in an incomplete form. The conclusion at which the author has arrived is as follows. Whenever, under the conditions of experiment, two allotropic forms of the dissolved or fused substance can exist, then supersaturation or superfusion, as the case may be, is also possible. In other words, allotropy is the cause of supersaturation. The term allotropy is used in a wider sense than usual; here it includes different crystalline or amorphous forms of a body brought about by the presence or absence of foreign molecules, and the statement is therefore applicable to cases of supersaturation involving hydrated salts, and also double salts. The experimental evidence in favour of the above, though incomplete, is already fairly large. The law is found to hold good not only with hydrated salts, but also with salts crystallising usually without water and with numerous organic compounds. Thus, allotropic forms have been found, and supersaturated solutions prepared, in the case of potassium nitrate, ammonium nitrate, silver nitrate, acetonilid, hydroquinone, acetamide, malonic acid, mandelic acid, resorcin, tartaric acid, citric acid (four modifications), and sodium chlorate, this last observed first by Ostwald. The author intimated his intention to examine further as to the limits, and to investigate the border region in which supersaturation can be terminated by shock or other mechanical means.—A paper on the geometrical investigations of the circular functions of 3θ and 5θ, by Prof. Anglin.—On some nuclei of cloudy condensation, by John Aitken, F.R.S. It has been claimed, the author said, by Helmholtz and Richarz, that "ions" were active in producing condensation in supersaturated vapour, and that these, along with dust, produced the ordinary cloudy condensation in the atmosphere. In an experiment by the author to test this conclusion, hydrogen was burned in filtered air, when it was found that, if precautions were taken to have the hydrogen pure and the air absolutely dust free, the ions lost their power of producing cloudy condensation as soon as they were cooled. The products of combustion remained free from condensed particles, when expanded, and when the products were tested by means of steam near the combustion-chamber, while they were still hot, they showed very little power of condensing. It had been shown in a previous paper that sunshine gave rise to a great increase in the number of particles under certain conditions, and experiments, recently made, were described in which it was shown that, though sunshine has no effect in producing nuclei in ordinary air, yet, if any of the so-called impurities in the atmosphere be present there in the gaseous condition, the sunlight produces a great number of nuclei. It was found that if ammonia, peroxide of hydrogen, nitric acid, nitrous acid, or sulphurous acid, were present in the air, sunlight caused the formation of a great number of nuclei of condensation, showing that if any of these gases are present in the air, clouds would be produced, though there was no dust present, if the air became saturated.

PARIS.

Academy of Sciences, May 10.—M. A. Chatin in the chair.—The President announced the losses the Academy had sustained by the deaths of M. Des Cloizeaux and Mgr. le duc d'Aumale.—Explanations of some experiments of M. G. Le Bon, by M. Henri Becquerel. Experimental evidence is given showing that vulcanite is transparent to the red and infra-red rays, which, although without action upon an unexposed plate, are capable of continuing the action of the actinic rays upon a plate which has been exposed for a very short period of time. These red rays are also capable of destroying the phosphorescence of zinc sulphide, and their passage through the vulcanite affords a complete explanation of the observations of M. G. Le Bon, the assumption of the existence of a special kind of light, "dark light," being unnecessary.—On solutions of acetone and their explosive properties, by MM. Berthelot and Vieille. This paper is a lengthy one, and gives the pressures of acetylene dissolved in acetone at different temperatures and concentrations, the conditions under which dissolved acetylene explodes; and also acetylene gas in contact with its solution in acetone.—Remarks on the explosive decomposition of solutions of acetylene, by MM. Berthelot and Vieille. In the explosive decomposition of solutions of acetylene in acetone, the latter is also broken up into carbon, hydrogen, water, and the two oxides of carbon.—On some conditions of propagation of the decomposition of pure acetylene, by MM. Berthelot and Vieille. It was found to be impossible to obtain a critical pressure below which the propagation of the explosive wave did not take place, as in a series of experiments at a given pressure the wave was sometimes produced and sometimes not.—On the employment of four-dimensional space in the study of algebraic surfaces admitting several series of conics, by M. Eugène Cosserat.—On an analytical formula relating to certain integrals of elliptic functions with respect to their modulus, by M. F. de Salvert.—On the algebraic integration of linear differential equations of the third order, by M. A. Boulanger.—On the solubility of liquids, by M. A. Aignan. The method of Alexejew for the study of the mutual solubility of liquids is criticised, and a new method suggested which leads to a different definition of the coefficient of solubility. The formulæ deduced are applied experimentally to the case of ether and water.—On multiple resonance, by M. L. Décombe. The experiments cited entirely confirm the theory of resonators put forward by Poincaré and Bjerknes.—On the diurnal variation in the direction of the wind, by M. Alfred Angot. In order to get rid of the disturbing effects of surrounding buildings, the observations were carried out at the top of the Eiffel Tower.—Basic salts of cadmium, by M. Tassilly.—Researches on strontium sulphide, and on the method of obtaining it highly phosporescent, by M. José Rodriguez Mourelo. The sulphide is prepared by heating a mixture of strontium carbonate, sulphur, sodium carbonate, sodium chloride, and bismuth sub-nitrate.—Thermal study of the sodium derivatives of acetylene, by M. Camille Matignon.—Contribution to the study of the preparation of ordinary ether, by M. L. Prunier. Some sulphonic acids are always present in addition to the sulphate and ethyl sulphate previously noted.—Action of chloral hydrate upon phenylhydrazine. Diphenylglyoxazol and its derivatives, by M. H. Causse.—On the effect of manganese in the oxidations induced by laccase, by M. Gabriel Bertrand. The presence of a manganese salt increases the

oxidising power of laccase to a remarkable extent. The author points out that the presence of minute traces of manganese in plants may be of great physiological importance.—On the fauna of the pools on the eastern coast of Corsica, by M. Louis Roule.—On a disease of orchids caused by the *Glœosporium macropus*, Sacc., by M. Mangin. After detailing the methods employed in ascertaining the presence of the *Glœosporium* in the affected plants, measures are suggested for fighting the disease, chiefly the use of β-naphthol.—On the mode of formation of the primary dunes of Gascony, by M. E. Durègne.—On the general course of glacial denudation, by M. Stanislas Meunier.—Experiments showing that the liver destroys dissolved hæmoglobin, and that it keeps the iron, by M. Louis Lapicque.—The number of poisonous principles produced by a pathogenic microbe, by M. A. Charrin. The idea is attacked that a specific pathogenic organism produces one specific poisonous principle, its toxin, and experiments are quoted to show that one and the same species of microbe can produce several pathogenic compounds. Thus the pyocyanic bacillus is shown to produce several, easily distinguishable by their pathological effects.—On barley, by M. Balland. Some proximate analyses of barley.—On the dialysis of the alkaline humates, by M. J. Dumont.—Remarks on some properties of the oxydase in wines, by M. Bouffard.—Research on caramel. Possible confusion with coal tar-colours, by M. Antonio J. da Cruz Magalhaes.

DIARY OF SOCIETIES.

THURSDAY, MAY 20.

ROYAL SOCIETY, at 4.30.—Bakerian Lecture—On the Mechanical Equivalent of Heat: Prof. Osborne Reynolds, F.R.S., and W. H. Moorby.

SOCIETY OF ARTS, at 4.30.—Kerman and Persian Beluchistan, with special reference to the Journeys of Alexander the Great and Marco Polo: Captain P. Molesworth Sykes.

CHEMICAL SOCIETY, at 8.—The Theory of Osmotic Pressure and the Hypothesis of Electrolytic Dissociation; Molecular Rotation of Optically Active Salts; Heats of Neutralisation of Acids and Bases in Dilute Aqueous Solution: Holland Crompton.—The Platinum-Silver Alloys: their Solubility in Nitric Acid: John Spiller.—A Comparative Crystallographical Study of the Normal Selenates of Potassium, Rubidium and Caesium: A. E. Tutton.

FRIDAY, MAY 21.

ROYAL INSTITUTION, at 9.—Contact Electricity of Metals: Lord Kelvin.

SOUTH-EASTERN UNION OF SCIENTIFIC SOCIETIES (Tunbridge Wells), at 3.30.—What can be done to save our Fauna and Flora from unnecessary Destruction? : Rev. J. J. Scargill and A. Rose.—How can the Technical Education Grant assist Local Scientific Societies? S. Atwood and J. W. Tutt.—Local Museums: Practical Observations on Objects and Methods: W. Cole and E. A. Pankhurst.

EPIDEMIOLOGICAL SOCIETY, at 8.

SATURDAY, MAY 22.

ROYAL BOTANIC SOCIETY, at 4.

GEOLOGISTS' ASSOCIATION—Excursion to Erith and Crayford. Director: Flaxman C. J. Spurrell. Leave Cannon Street (S. E. R.) at 2.2.

LONDON GEOLOGICAL FIELD CLASS.—Excursion to Tunbridge Wells. Wealden Beds. Leave Cannon Street, 2.23: arrive Tunbridge Wells, 3.40.

SOUTH-EASTERN UNION OF SCIENTIFIC SOCIETIES (Tunbridge Wells), at 11.—The Committees of Field Clubs: Prof. G. S. Boulger.—Current Bedding in Clay: Section at New Athletic Ground, Tunbridge Wells: Prof. H. G. Seeley, F.R.S.—Search for Coal in the South-east of England: H. E. Turner and W. Whitaker, F.R.S.—History of the Weald in special reference to the Age of the Plateau Deposit: W. J. Lewis Abbott.

MONDAY, MAY 24.

SOCIETY OF ARTS, at 8.—Design in Lettering: Lewis Foreman Day.

LINNEAN SOCIETY, at 3.—Anniversary Meeting.

TUESDAY, MAY 25.

ROYAL INSTITUTION, at 3.—The Heart and its Work: Dr. E. H. Starling.

ROYAL STATISTICAL SOCIETY, at 5.30.

ANTHROPOLOGICAL INSTITUTE, at 8.30.—A Quinary System of Notation used in Luchoo: Prof. Basil Hall Chamberlain.—Ancient Measures in Prehistoric Monuments: A. L. Lewis.——*Probable* Papers: Further Discoveries of Stone Implements in Somaliland: H. W. Seton-Karr.—The Berbers of Morocco: W. B. Harris.—Rock Paintings and Carvings of Australian Aborigines: R. H. Mathews.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—The Optical Effects of Intensification: Chapman Jones.—Some Notes on the Correct Rendering of the Colours of Flowers: H. T. Malby.

ROYAL VICTORIA HALL, at 8.30.—Growth of the Colonies in the Queen's Reign: O'Donnell.

WEDNESDAY, MAY 26.

GEOLOGICAL SOCIETY, at 8.—On Augite-Diorites with Micro-Pegmatite in Southern India: T. H. Holland.—The Laccolites of Cutch and their Relation to the other Igneous Masses of the District: Rev. J. F. Blake.

BRITISH ASTRONOMICAL ASSOCIATION, at 5.

THURSDAY, MAY 27.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Annual General Meeting.

FRIDAY, MAY 28.

ROYAL INSTITUTION, at 9.—The Isolation of Fluorine: Prof. H. Moissan.

PHYSICAL SOCIETY, at 5.

SATURDAY, MAY 29.

LONDON GEOLOGICAL FIELD CLASS.—Excursion to Sheerness. Drive to East Church, Hensbrook. London Clay. Leave Holborn Viaduct, 1.25.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Exercises in Practical Physiology: Dr. A. D. Waller, Part 3 (Longmans).—Milk and its Products: Prof. H. H. Wing (Macmillan).—The Theory of Electricity and Magnetism: Prof A. G. Webster (Macmillan).—The Elements of Physics: E. L. Nichols and W. S. Franklin, Vol. 3 (Macmillan).—Prehistoric Problems: Dr. R. Munro (Blackwood).—A Great Agricultural Estate: The Duke of Bedford (Murray).—The Localisation of Faults in Electric Light Mains: F. C. Raphael (*Electrician* Company, Ltd.).—The Birds of our Country: H. E. Stewart (Digby).—Handbook for Jamaica for 1897 (Stanford).—Reports from the Laboratory of the Royal College of Physicians, Edinburgh, Vol. 6 (Edinburgh, Clay).—Memories of the Months: Sir H. Maxwell (Arnold).—Government of India, Department of Revenue and Agriculture. Accounts of the Trade carried by Rail and River in India, 1895–96, and the Four Preceding Years (Calcutta).—Electromoteurs et Leurs Applications: G. Dumont (Paris, Gauthier-Villars).—The Development of the Frog's Egg: Prof. T. H. Morgan (Macmillan).—Flowering Plants: Mrs. A. Bell (Philip).—First Stage Mechanics of Fluids: Dr. G. H. Bryan and F. Rosenberg (Clive).—Social Transformations of the Victorian Age: T. H. S. Escott (Seeley).—Topographische Anatomie des Pferdes: Profs. Ellenberger and Baum, Dritter Teil (Berlin, Parey).—Report on the Geological Structure and Stability of the Hill Slopes around Naini Tal: T. H. Holland (Calcutta).—Leçons sur L'Electricité et le Magnétisme: Prof. E. Mascart, tome deuxième (Paris, Masson). Essai sur les Éléments de la Mécanique des Particules: H. Majlert, 1re Partie: Statique Particulaire (Neuchatel, Attinger).

PAMPHLETS.—Geological Survey of Canada: Report on the Country between Athabasca Lake and Churchill River: J. B. Tyrrell and D. B. Dowling (Ottowa).—Ditto: Report on Explorations in the Labrador Peninsula along the East Main, &c., in 1892, 1893, 1894, and 1895: A. P. Low (Ottawa).—Resultate aus den Beobachtungen des Veränderlichen Sternes η Aquilae: W. J. S. Lockyer (Göttingen).

SERIALS.—Transactions of the Astronomical and Physical Society of Toronto, 1896 (Toronto).—Palæozoic Fossils: J. F. Whiteaves, Vol 3, Part 3 (Ottawa).—Engineering Magazine, May (Tucker).—Proceedings of the Royal Society of Victoria, Vol. ix., new series (Melbourne).—Quarterly Journal of the Geological Society, Vol. liii Part 2, No. 210 (Longmans).—General Index to the First Fifty Volumes of the Quarterly Journal of the Geological Society, Part 2 (Longmans).—Journal of the Institution of Electrical Engineers, No. 128, Vol xxvi. (Spon).—Memoirs of the Geological Survey of India. Palaeontologia Indica, ser. xvi. Vol. 1, Part 1 (Calcutta).—Memoirs of the Geological Survey of India, Vols. xxv. and xxvi. (Calcutta).—History of Mankind: F. Ratzel, translated, Part 19 (Macmillan).—American Naturalist, May (Philadelphia).—Journal of the Franklin Institute, May (Philadelphia).—Psychological Review, May (Macmillan).—Ditto, Psychological Index, No. 3 (Macmillan).—Journal of the Chemical Society, May (Gurney).—English Illustrated Magazine, June (198 Strand).

THURSDAY, MAY 27, 1897.

THE COLLECTED PAPERS OF PROFESSOR ADAMS.

The Scientific Papers of John Couch Adams, M.A., Sc.D., D.C.L., LL.D., F.R.S., late Lowndean Professor of Astronomy and Geometry in the University of Cambridge. Vol. i. Edited by W. G. Adams, Sc.D., F.R.S. With a memoir by J. W. L. Glaisher, Sc.D., F.R.S. Pp. liv+502. (Cambridge: University Press, 1896.)

TO collect with completeness, and to edit with care and reverence, the scientific work of those whom the world has followed with close and respectful attention, must be a grateful and, at times, a necessary task. The opportunities of publication are fortunately numerous, for many learned societies and scientific bodies are eager to make known the researches of those whom they are proud to reckon among their associates or supporters. Obviously, this general scattering is attended with many evils, which collection will effectually remove. Not only will readier access be given to the student to those papers in which he is interested, but the reputation of the author will probably be enhanced by the greater coherency which his work is likely to acquire. In the present instance, however, though the result will be welcomed by many, the necessity for collection is not so apparent as in some other famous cases. The number of published papers is not large—sixty-two in all, of which five are addresses from the presidential chair to the recipients of the medals of the Royal Astronomical Society, and a few others, the results of observations connected with the direction of the Cambridge Observatory. Of the more important papers, each is usually complete in itself, since it was seldom necessary for Adams to return to a subject which he had once discussed. Neither did Prof. Adams select many channels by which to make his thoughts and results known to the world. The Astronomical Society sufficed him for the greater part, and their publications are readily accessible, though it must be admitted that the Council of that Society have very recently found themselves compelled to republish one of his more interesting papers.

Dr. Glaisher contributes an appreciative account of Adams's life. Without containing many new facts, it shows a keen insight into his character, and makes the reader understand in some measure, the reason why Adams maintained so pre-eminent a position among his contemporaries. The thoroughness with which he did his work, the innate craving after perfection, the steady maintenance of a high standard of excellence, the dislike to hurried and incomplete publication, all contributed to give him that superiority which he never courted, and to make him an authority whom all respected. Naturally, the history of the discovery of Neptune figures largely in the biographical notice. It is a subject that apparently never wearies, and concerning which the last word will never be written. But all the material facts have long since been threshed out, and there is no new source from which any fresh information can be derived. Dr. Glaisher permits himself to criticise in some particulars the conduct of both Airy and Challis.

"Adams was not fortunate," he says, "in the two astronomers to whom he communicated his results; neither of them gave to a young and retiring man the kind of help or advice that he should have received. . . . As Professor in the University, he (Challis) should not have allowed a young Senior Wrangler, through modesty or diffidence, to do such injustice to himself. . . . It is impossible not to contrast the admiration with which he (Airy) received Le Verrier's published writings with the indifference shown towards Adams's still unpublished work. Adams was certainly as clearly convinced of the reality of the planet as Le Verrier, and whatever claims the latter has to the name of philosopher rather than mathematician, apply equally to the former."

This is no doubt true, but it does not seem to be as distinctly remembered as it should be that Adams in fame and reputation suffered no irreparable injury. Greater attention could not have been drawn to the excellence and originality of his work, or the philosophic character of the original conception, than was occasioned by the untoward circumstances that surround the discovery of Neptune. Though no one sought less for public applause than did Adams, the effect of the controversy was to advertise his merits far more widely than would have been the case, if Le Verrier's papers had not appeared. The immediate effect was to place Adams at one bound in the front rank of astronomers; and perhaps there is no other instance, in scientific life, of a reputation so assured being so swiftly won. He presents the singular—perhaps the unique—instance of a young man being unable to add to his rapidly acquired reputation. That the high level at which he commenced his career was amply sustained, will of course be universally admitted; but it was almost impossible that it could be raised, in the public mind, at least.

The investigation of the perturbations of Uranus, of course, occupies the first place in the collected series of papers; and to this discussion is added, as a matter of historical interest, some of the earliest observations of Neptune made by Prof. Challis, as well as an account of the zonal measurements made at the instance of the late Astronomer Royal, with a view to the detection of the planet prior to the actual discovery at Berlin. More interest, however, attaches to a reference to a reprint of Adams's original paper in Liouville's *Journal de Mathématiques* for 1875, because it is accompanied by a less known note, that Prof. Adams contributed in reply to some criticisms of Prof. Pierce. Very shortly after the discovery of the planet, Prof. Pierce had contended that the true period of Neptune differed so widely from that assigned by Adams to the hypothetical planet, that the discovered object was not the planet indicated by geometry, and that in fact its discovery must be regarded as a happy accident. The main contention of Prof. Pierce was that the commensurability of the mean motion of Uranus with that of Neptune would give rise to perturbations always in the same part of the orbit of the inferior planet, whereas the perturbations due to the hypothetical planet would not occur with the same regularity, but would vary 80° upon the orbit of Uranus, at each successive conjunction and opposition. Adams had little difficulty in disposing of this criticism, though

this collection of papers would indicate that he took no notice of it for thirty years. He then points out that the objection would be valid if it were sought to explain the perturbations of Uranus throughout one or more whole synodic periods of the planet. Practically, and for the purposes of the particular solution, the action of the disturbing planet on the motion of Uranus is limited to some twenty years before and after 1822, when the two planets were last in conjunction. The preceding conjunction took place in 1650, some forty years before Flamsteed's earliest observation, and the sensibly elliptic orbit in which Uranus was moving from that time to the beginning of the century, was the elliptic orbit on which the perturbations of Neptune at the last conjunction had been impressed. The outstanding discrepancy exhibited by Flamsteed's observation, in 1690, from the place indicated by the theories of both Adams and Le Verrier, arose from the inadequacy of those theories to represent the place of the planet in the remote past, owing to the erroneous distance assigned to the hypothetical planet.

Passing over a few short papers generally referring to the orbits of comets and of double stars, we come to Adams's work on the Moon. The papers on this subject refer to lunar parallax, the secular acceleration of the moon's mean motion, and critical notices on the lunar theory, both theoretical and numerical. The work on lunar parallax includes an entire revision of the equations from which the parallax is deduced in the tables of Burckhardt and Damoiseau, as well as in the theories of Plana and Pontécoulant. Henderson had found a difference of $1''\cdot3$ in the value of the mean parallax deduced from observation, according as he employed the tables of Damoiseau or Burckhardt. Clausen had also called attention to discrepancies in the equations of parallax between the same two authorities, but had not pursued the subject, probably on account of the labour involved. But Adams not only instituted a rigorous comparison between the coefficients employed, and traced the errors of Burckhardt to their source, but added a table of corrections to the daily values of the parallax given in the Nautical Almanac from 1840–1855. This heavy piece of work, demanding as much nicety in its mathematical investigation as patience in its numerical application, Dr. Glaisher describes as characteristic of the author. No part of the work is given; the method of procedure is briefly sketched, and the final conclusions are stated in the fewest words, and simplest manner possible.

The discussion of the secular acceleration of the moon's mean motion is known almost as well as the history of the discovery of Neptune. Fierce controversy has centred round this question, and forced it on public notice. It is difficult to understand now, and impossible to explain briefly, the reason for the controversy called forth by Adams's paper in 1853. This somewhat acrimonious debate was carried on with undiminished force for some years, though Adams took little part in it beyond practically settling the fray in 1860. To Adams, and to mathematicians of the present day, the problem is purely one of dynamics. Given that the eccentricity of the earth's orbit changes at a slow uniform rate, to determine the corresponding rate of change in the mean motion of the moon. The solution of this problem is, as Adams pointed out, to be effected by means of a purely algebraical process, the validity of each step of which, admits of being placed beyond all possible doubt. Here there would seem to be no room for dispute. But the question did not present itself quite in this simple manner to Laplace and others of his time. They always had before them the necessity of explaining on purely gravitational grounds the observed motion of the moon. The complete vindication of the Newtonian theory was dear to the hearts of the schoolmen of the last century. Many triumphs had been successively won by investigations undertaken with this object, the greatest of which was due to Laplace, who was believed to have satisfactorily explained and laid to rest the last difficulty, revealed by the complicated motion of the moon. In his paper of 1853, Adams joined issue with Laplace, and in showing that the work of the earlier astronomer was incomplete, he not only destroyed the harmony that was so long supposed to exist between observation and theory, but practically impeached the judgment of those who upheld the authority of Laplace. M. de Pontécoulant seems to have urged, as a reason for the non-acceptance of Adams's value, the fact that it had "l'inconvénient d'altérer profondément l'expression analytique admise jusqu'à present, au coefficient de cette equation."

It is curious to reflect on what slender grounds the observed value of $10''$ assigned to the secular acceleration was based, and, consequently, how little increased weight it could add to any theoretical value with which it chanced to accord. We may take Dunthorne's investigation as typical of the others made with the same purpose. He computed from the lunar tables in use in his time, probably those published in 1739, and in which the moon's centennial mean motion would have a considerable error, the circumstances of the eclipses recorded by Tycho Brahe, by Regiomontanus (1478–1490), by Ebn Jounis (977–8), the eclipse of Theon (364), and those of Ptolemy. Not one of these sources is unobjectionable, or possesses the necessary accuracy. Ptolemy's catalogue of eclipses was probably selected by him to satisfy a preconceived theory. Theon says that he computed the time of the beginning of the eclipse, and found the observation agreed with his calculation. This agreement is suspicious. The Arabian observations, eye determinations of the beginning and end of the phenomena, are the best suited to the purpose; though here the error in the moon's mean longitude must be considerable, and a secular acceleration of $7''$ will satisfy the observations. Those of Regiomontanus and Tycho Brahe, still made without a telescope, must have approximately the same error, and are too near in point of time to gain the advantage of accumulation.

It is scarcely necessary now to point out the source of the error in Laplace's theory. In this error he was followed by Damoiseau and Plana, who, while extending the method to include the square and higher powers of the disturbing force, failed to detect the incompleteness of the reasoning which vitiated the earlier portion of the work. Laplace only took into account directly the radial component of the disturbing action of the sun.

This neglect of the tangential disturbing force, or the assumption that the area described in a given time by

the moon about the earth undergoes no permanent alteration, introduced a considerable error in the coefficient of m^4 in the expression for the true longitude. Correcting the whole of the coefficients in the expansion as far as m^7, Adams assigned a value to the secular acceleration that has not been sensibly disturbed by any subsequent investigation. This value is 5"·7, a quantity only about one-half of that assigned by Laplace, or of that which seemed to be demanded by observation. The minuteness of the quantity sought affords a good illustration of the powers of analysis. The acceleration of the moon's motion implies, of course, an approach to the earth, but the amount is less than one inch per annum, and this minute quantity is determined by theory to within about one-thousandth part of its true amount.

Such an investigation as this last, exhibits the patient examination which Adams was prepared to give to a term, the value of which has been frequently under review by methods that have long been pursued. It shows a confident reliance upon the accuracy of his judgment, the completeness of his work, and a refusal to be led by authority. But some later papers on the general method of treating the lunar theory will be better appreciated, as showing, perhaps, greater originality, and illustrating the application of the results of more modern mathematical inquiry to obtain greater accuracy with less expenditure of labour. It is curious to notice that but for a lucky accident, this peculiar method of treating the lunar motion, and which is likely to be much developed in the future, would not have been published by Adams himself. In 1877, Mr. Hill published his inquiry into the motion of the moon's perigee, in which is sought an absolutely accurate value of that part of c (the ratio of the synodic to the anomalistic months) which depends upon m alone. This is the historic problem that Clairaut successfully solved by adding the term depending upon m^3, and thus supplying a confirmation of the Newtonian theory when it was most needed. Delaunay has since determined the numerical value of the series as far as m^9, and possibly human patience could get little further by this process. Mr. Hill had recourse to quite a different method, which, as applied, gives the same accuracy that would be attained by carrying the series to m^{27}. The sight of this paper by Mr. Hill, seems to have reminded Prof. Adams that some ten years previously he had been at work on similar lines in order to arrive at an accurate value of g, which is related to the motion of the node in the same way that c is to the perigee. The differential equation which determines z, the moon's coordinate perpendicular to the ecliptic, is

$$\frac{d^2z}{dt^2} + \left(\frac{\mu}{r^3} + \frac{\mu'}{r_1^3}\right)z = 0.$$

Prof. Adams puts

$$\frac{\mu}{r^3} + \frac{\mu'}{r_1^3} = (n - n')^2\{q^2 + 2q_1 \cos 2(n - n')t + 2q_2 \cos 4(n - n')t + 2q_3 \cos 6(n - n')t + \&c.\},$$

and on solving this equation was led to the form that Mr. Hill had employed in his work. For Mr. Hill had made the general equations of motion depend upon a single differential equation having the form

$$\frac{d^2w}{d\tau^2} + \Theta w = 0,$$

where τ denotes the mean angular distance between the sun and moon, and Θ can be developed in a periodic series of the form

$$\Theta_0 + \Theta_1 \cos 2\tau + \Theta_2 \cos 4\tau + \&c.,$$

leading to the same infinite determinant in both cases. This is developed in a series of powers and products of small quantities, the coefficient of each term being given in a finite form. The similarity of method pursued independently by the two mathematicians, and the greater accuracy obtainable with less labour, seem to point to a new departure in the method of treating the lunar theory. Prof. Adams has indicated what appears to him the most advantageous method of treating this problem.

We can but barely mention one other of Adams's investigations, the discussion of the orbit of the November meteors. It is well known that the late Prof. Newton left undecided the periodic time in which the meteors revolved about the sun, indicating, however, the method which might lead to the settlement of the question by the discussion of the observed amount of secular perturbation of the node. By a method given by Gauss in his "Determinatio Attractionis," it is shown how to determine the attraction of an elliptic ring, such as the meteors form, on a point in any given position. By dividing the orbit of the meteors into a number of small portions, and summing up the changes corresponding to these portions, Adams found the total secular changes of the elements produced in each of the five possible periods that Prof. Newton showed might be assigned as the meteoric path. With only one of these periods, that of about thirty-three years, was it possible for the node to advance in the manner required by the several historical accounts of the meteoric display. With a thirty-three years' period, and with no other, the longitude of the node is increased 20' by the action of Jupiter, 7' by that of Saturn, and 1' by Uranus, thus 28' in all, giving a mean annual motion of 52", agreeing with the observed motion, and thus satisfactorily settling the periodic time in which the November meteors revolve.

Several other papers possess great interest, and evidence among other things much painstaking arithmetic. Such is the calculation of thirty-one of Bernoulli's numbers, and the computation of the Eulerian constant to 263 places of decimals. These may have been the occupation of his leisure moments. The reputation of Adams will ever rest upon the determination of the inverse perturbations of Uranus, the work on the lunar theory, and his inquiry into the period of the November meteors.

A CYCLOPÆDIA OF BIOLOGICAL THEORY.

Les Théories sur l'Hérédité et les grands problèmes de la Biologie générale. Par Yves Delages, Professeur à la Sorbonne. Pp. xiv + 878. (Paris: Reinwald, 1895.)

PROFESSOR DELAGES has produced in this large volume of 880 pp. royal octavo, a valuable exposition and critical discussion of the modern theories bearing upon the great problems of biology. The work is remarkable for the ability with which so vast a variety of theories and observations are epitomised and considered. Whilst the author does not profess to give

more than an outline of the chief doctrines concerned, it is the fact that there is no treatise in English or German which contains so useful a review of biological theory. Written as it is, with a patriotic motive—namely, that of inducing the rising generation of French zoologists to occupy themselves with the general theories (such as those of Darwin, Wallace, Weismann, Spencer, Naegeli, and others) which have, as he justly states, received far more attention in this country and in Germany than in France—the book should prove of very great value also to English students. This is sufficient excuse for now drawing attention to Prof. Delages' volume, although it was published more than a year and a half ago. So far as I am aware, it is not so widely known in this country as it should be on account of its comprehensive and thoroughly interesting character.

It is true that the preface to his work has caused some disagreement among the Professor's own colleagues. M. Delages in severe terms expresses his disapproval of the old school of zoological and botanical studies. He points out (and I think justly) that whilst French men of science have taken a leading part in the development of biological doctrine and methods of study during the century, yet that there has been during the past twenty years in France a tendency to "une fausse direction des recherches biologiques." For works or memoirs of importance bearing upon the great problems of general biology, there are, says M. Delages, for every one written in French, three in English and ten in German. He attributes this to the fact that French students have not had their attention sufficiently directed to these great problems. Accordingly, by a very remarkable effort, he has produced the present work which shall (and in my opinion does) serve as a cyclopædia of biological theory, by aid of which the French student may be introduced to this hitherto neglected field, and led to study for himself original authorities. In fact Professor Delages has, first of all by diligent study, corrected for himself what he regards as the defect in the current education of a French zoologist, and then has embodied his valuable abstracts and critical notes in the volume which he offers to the young men who come after him.

In spite of the fact that there are others in France who have recognised, as does M. Delages, the importance of modern theories in biology as stimulating and directly producing new observations, and thus building up the fabric of biological science, yet, on the whole, I am convinced that M. Delages is right, and that such a book as his was needed and will be very fruitful in France. It is so good a book that it will be of great service also in England.

It is true that M. Delages seems to have forgotten for a moment, in speaking of the growth of histological technique as foreign to France, that Ranvier, of the Collège de France, is one of the most original and fertile discoverers in this field at present living. It is also true that his colleague, Prof. Alfred Giard, who is surrounded by an enthusiastic band of disciples, has for many years taken actually the same attitude as that adopted by Prof. Delages, and has proclaimed the importance of the new theories, and insisted, not only by precept, but by example, on the necessity of carrying on observation and experiment in zoology in order to test hypothesis, and to determine the truth or error of current theory, rather than let them take the form of exact but meaningless record of facts, pointing to no general conclusion. None the less, it seems to me that Prof. Delages' contention is true, and that, in spite of brilliant exceptions, biological science has too often followed a false direction in France (and no doubt in England also), owing to an ignoring of the great search-lights of theory which happen to have originated outside France. The tendency to which Prof. Delages alludes was sufficiently obvious to those who were able to watch, as many still alive did, the reception of Darwin's theory of the origin of species by natural selection in France, on the one hand, and in Germany on the other. There can be no doubt that the publication of M. Delages' book is evidence of the fact that what may be called "modern biological theories" are now receiving due attention in France, and that the brilliant originality and independence of thought, as well as honesty and ingenuity of observation which characterise French men of science, will more and more be directed to the solution of those great problems which occupy the attention of the biological world at large.

A brief sketch of the contents of Prof. Delages' book is all that the space of this article permits me to give. It is divided into four parts: Part i. The Facts; Part ii. Special Theories; Part iii. General Theories; Part iv. The Theory of Actual Causes. Under Part i. are treated (1) *The Cell:* its constitution, its physiology, its reproduction; an admirable *résumé* in ninety pages of the recent work, both on karyokinesis and the physiology of protoplasm. (2) *The Individual:* regeneration, grafting, generation, ontogeny, alternation of generations, sex and secondary sexual characters, latent characters, teratogeny, correlation, death and continuity of life, the germ-plasma. (3) *The Race:* heredity, variation, the formation of species. Under Part ii. we find statements of the following theories. (1) Speculative theories as to the structure of protoplasm and the cause of its movements, viz. the theories of Berthelot, of Verworn, of Quincke, and of Butschli; (2) theories of cell-division; (3) theories of regeneration; (4) of polar globules; (5) of sexual generation; (6) of the ontogenetic process; (7) of the parallelism of ontogeny and phylogeny; (8) of the origin of sex; (9) of teratogeny; (10) of death and of germ-plasma; (11) of heredity; (12) of the transmission of acquired characters; (13) of latent characters; (14) of telegony; (15) of hybridity; (16) of variation; (17) of the formation of species.

Under Part iii. we have statements and brief, but trenchant, criticism of the theories of "animism," "evolutionism" (spermatists and ovists), and "micromerism." Under the last term are included and considered the views of Buffon, Béchamp, H. Spencer, Haacke, Dolbear, Erlsberg, Haeckel, His, Cope, Orr and Maulia, and many others, including that of "ancestral plasmas" (Weismann), pangenesis (Darwin), stirpes (Galton), whilst "organicism" is the term applied to the theory of Descartes and to the auto-determination of Roux.

In the fourth and last Part are given "Idées de l'auteur," a retrospect and review of much of what has been already treated at greater length, with the definite introduction of the author's own conclusions. By this method of division

of his work, Prof. Delages has very successfully made clear to his reader the facts under consideration, the theories which have been advanced in relation to those facts, and finally his own judgment as to what is sound and permanent and what erroneous in current theories; whilst those theoretical views which are novel, and here put forward for the first time by himself, are kept distinct. A bibliographical index, of eighteen closely-printed pages, completes the work; and with regard to this long and useful list of books and memoirs, I may say that the impression given to a reader of M. Delages' book is that he has not merely cited the titles of this large mass of literature, but has actually performed the heavy task of reading and critically estimating each work thus catalogued.

It is, of course, inevitable that such a task as that undertaken by the author should not be accomplished without some omissions and some mistakes; but it is no little merit to have performed such a task conscientiously, as it has here been performed. The criticisms advanced by M. Delages may not always be those which commend themselves to another biologist; his own theoretical views, though always philosophical and worthy of full attention, may not be necessarily acceptable in every case. Yet the value of the work is not lessened by such considerations. He is no dogmatist, and candidly declares that the theories, which he for the present accepts, are open to correction and replacement with the progress of knowledge. The worthy and useful object of the book is, in short, not to impose a set of theories on the reader's mind, but to interest him in the theoretical aspects of biological phenomena, and to assist him, as far as may be, in arriving at theoretical conceptions which may guide his investigations, if he be a naturalist, or furnish him with a key to the more popular discussions of biological problems, should he be merely a philosopher, or even "un homme curieux des choses de la science." It is a book which should be read and closely studied by every young biologist. The full and comprehensive treatment of the subject has resulted in what must appear a formidable volume equivalent to some three or four modern manuals; yet the reading of it will be found to entail but little effort, on account of the lucidity of the author's method and the unflagging interest which he himself evinces in the successive sections of his work. It is, after all, a distinct pleasure to see English and German theories formulated in the clear logical phrases of the French language.

E. RAY LANKESTER.

COMPARATIVE MYTHOLOGY.

Contributions to the Science of Mythology. By F. Max Müller. Vol. i. Pp. xxxvi + 426. Vol. ii. Pp. ix + 427–864. (London: Longmans, 1897.)

IT has for some time past been tolerably well known by many that Prof. Max Müller was working at a treatise on comparative mythology, and with others we have been anxiously awaiting the appearance of the "last word" on the subject by the eminent Oxford professor. General interest in the matter has, moreover, been excited to a more than usual extent by the comments made upon the last edition of "Chips from a German Workshop" by writers for the press and others, for all felt that the veteran expounder of dead and gone beliefs would rise in his might and rend certain of his critics who boldly stated that he stood alone, and was the only defender of a set of dying and dead theories. It seems that Prof. Max Müller hesitated for some time before he decided to publish the 864 octavo pages which form his present work, for he had almost made up his mind that he had arrived at a time of life when rest is more pleasant than work, and at a stage in his work where it was wise to stop and let the younger men carry it on in his place. Every reader of the volumes before us will be glad that the taunts of his enemies stung Prof. Max Müller into action, for, as he says, he had all along intended that his last work on comparative mythology should contain in a comprehensive form what he had hitherto written, and what he still wished to say, and he intended it to be the logical ending of a system of works which he had planned several years ago. On Language, Religion, and Thought he has already written learnedly and charmingly, and now that we have the volumes on the fourth subject, viz. Comparative Mythology, the system which Prof. Max Müller has elaborated is before us in its entirety. Those who seek for polemics or hostile observations upon critics and their rival theories will be disappointed in the perusal of this last section of the work, for he confines himself chiefly to re-stating his views and theories, and it is pretty clear that he has made up his mind to differ from his critics on fundamental principles and methods.

Prof. Max Müller quotes many great names in support of his views, and the general reader will find it very difficult to make up his mind which school he is to follow—the linguistic or the anthropological. The anthropological school holds that mythology is, on the whole, the narrative of the various grades through which the human race has advanced slowly towards what we call civilisation, and it proves many of its statements by drawing comparisions between the beliefs, manners and customs, and habits of savages which still exist on the earth, and those of the nations which have long since passed away.

Prof. Max Müller holds that mythology is the result of a period of moral decay, and a falling away from high moral and spiritual views; we must admit that our sympathies lie with the anthropological school, and we heartily wish that Prof. Max Müller had seriously set to work to classify and arrange the arguments which have been brought in line against him, and also that he had disproved many of the statements and facts alleged against his views. Some, too, will complain that little notice has been taken by him of the writings of men who, though they be his adversaries, are held in esteem by many thoughtful and intelligent people. With the details of the minor differences between the schools we have nothing to do, for, after all, they are only interesting to the experts themselves; we hear that Mr. Lang is about to write a refutation of the most recent expression of Prof. Max Müller's views, and we may be tolerably certain that the *minutiæ* of the subject will not be passed over.

It is but just to call attention to the great learning and skill with which Prof. Max Müller has arranged his

information, and the careful student will find scores of facts stated quite simply, and without any attempt to impress the reader, which could be found in no other book in the English language. Whether Prof. Max Müller be all right or all wrong, it must never be forgotten that he is a great linguist as well as an expounder of mythology, and that if some of us hold views other than his, we ought not to belittle the labours of the hard-working scholar who has done so much to explain to two generations of men the lessons which language has to teach. To write easily, accurately, and pleasantly of a difficult subject is a gift which is worth a great deal.

OUR BOOK SHELF.

The Story of the Earth's Atmosphere. By Douglas Archibald, M.A., Fellow and some time Vice-President of the Royal Meteorological Society. Pp. 208. (London: George Newnes, Ltd., 1897.)

THIS is one of the best of the Story series that we have read, but will probably not prove itself one of the most popular. If this prognostication prove correct, it will be because a large part of the public prefers to be amused rather than instructed. The author has endeavoured to compress too much information within the small compass at his command, and this design has in some measure destroyed the ease with which such a book should be read. The mechanics of the earth's atmosphere is not an easy subject for popular treatment, and though we cannot regret that the attempt has been made to give wider publicity to the work of Ferrel, Helmholtz, and Von Bezold, we cannot help feeling that the result would have been more satisfactory if the author could have given more space to his work, or had ventured to fill a larger canvas. The tale, on the whole, is pleasantly told, and the author is frequently able, from his wide travels, to illustrate his remarks by his own personal experience in climates where meteorological manifestations can be witnessed on a grander scale than in our own country.

Starting with the nature and chemical composition of the atmosphere, the author treats of the circumstances that affect its varying temperature. In this section some of the diagrams might have been a little clearer and a little more finished. The reference letters are in some cases barely legible. We notice, too, a curious sentence on page 52, which will puzzle the student: "As a general rule we find the greatest ranges of temperature of the lowest atmospheric stratum between day and night occur in the driest parts of the earth . . . where it often amounts to 40° F., and the smallest ranges in small oceanic islands, where it is as small as 50° F." From the remarks on temperature the author proceeds to discuss the winds and general circulation of the atmosphere, but the description of the more local phenomena of cyclones is deferred till after the consideration of precipitation. Some little improvement would, we think, result from a different arrangement of the chapters, which would not only have brought the same class of phenomena more closely together, but might have prevented the partial repetition of some of the facts contained in the earlier chapters. For example, two chapters on the sounds and colours of the atmosphere separate the one on cyclones from that relating to whirlwinds, tornadoes, &c., while the few remarks on dust and disease, in the last chapter, could possibly have found adequate expression in some of the others. But we willingly admit that Mr. Archibald had a very difficult task, and has accomplished it with a great measure of success. He was not willing to give a bare statement of facts, but has everywhere attempted to add an explanation of them. The book is written right up to date; and though some of the explanations may require modification as the study and science of meteorology advance, this is no impeachment of their present value, nor does it imply any fault on the part of the author.

W. E. P.

Wild Bird Protection and Nesting-Boxes, &c. By J. R. B. Masefield. 12mo, pp. 129. Illustrated. (Leeds: Taylor Brothers, 1897.)

ALL interested in the preservation of the feathered denizens of our woods, heaths, streams, and lakes (and who is not?), will give a hearty welcome to this useful, although unpretentious, little volume, which seems evidently the work of one well acquainted with his subject. After a short introduction, in which the author tells us that he has induced no less than six-and-thirty species to nest in his own garden, the book is divided into four chapters. The first deals with modern legislation on bird preservation, and the powers which a County Council can acquire for the purpose. In the second, we have a brief account of mediæval laws for the protection of those birds which were becoming scarce in early times. The third, and most generally interesting chapter, gives the author's experiences as to the best mode of attracting different kinds of birds to build; and the contrivances, which he describes so well and figures so admirably, will be found worthy of the best attention of those who may be inclined to devote their spare hours to this pursuit. In the fourth and final chapter, we find lists of the various species scheduled for special protection by different County Councils. From this we are glad to see that a very large percentage of these authorities have taken up the matter in good earnest. If a suggestion may be offered, it would seem preferable, in cases where a large number of species are scheduled, to include all the smaller birds, as otherwise none but a professed ornithologist can determine whether the order has been infringed. R. L.

Reports from the Laboratory of the Royal College of Physicians, Edinburgh. Edited by J. Batty Tuke, M.D., and D. Noël Paton, M.D. Vol. vi. Pp. 303. (Edinburgh: William F. Clay, 1897.)

A DESCRIPTION of the new laboratory of the Royal College of Physicians, Edinburgh, and a retrospect of the work done in the old laboratory, forms an introduction to this volume. The papers refer to investigations in anatomy, physiology, pathology, and pharmacology. Many of them are of too special a character to be usefully mentioned here, but among the subjects dealt with are: the relationship of the liver to fats, the action of large doses of dilute mineral acids on metabolism, acid and alkali albumin, influence of thyroid feeding on the proteid metabolism in man, the amount of iron in ordinary dietaries and in some articles of food, analyses of iron in the liver and spleen in various diseases affecting the blood, *Catha edulis*—a plant grown in parts of Arabia and Eastern Africa and widely used as a mild stimulant, carbonic acid gases in diseases of the alimentary tract (this paper brings out some interesting points as to the influence of carbonic acid gas upon digestion), and the Malayan arrow poisons.

First Principles of Natural Philosophy. By A. E. Dolbear. Pp. x + 318. (London: Ginn and Co., 1897.)

THIS elementary book is intended for those who wish to obtain some knowledge concerning the more generally recognised problems and principles pertaining to physics. With this object in view, the author has restricted himself to a simple exposition of the subject, and, with the further help of numerous illustrations and worked-out examples, the reader is made acquainted with the fundamental laws and principles relating to heat, optics, electricity, magnetism, &c. The mathematical treatment of the subject is, for the most part, laid on one side, only that of the most elementary character being attempted. The beginner, however, should get a fair insight into the subject if he uses this book as a first step to a more elaborate treatise, and in this respect it should find many readers.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Adjustable X-Ray Tubes.

THE writer has discovered a method of adjustment for X-ray tubes, somewhat different to those he has previously described, which possesses distinct practical advantages.

The arrangement is as shown in the illustration, and its essential feature consists in mounting the kathode upon a sliding support, so that it can be moved axially to a very small extent in and out of a tubular neck, blown on one end of a glass bulb. When arranged in this manner, the exact position of the kathode is found to have an enormous influence upon the penetrative value of the X-rays produced. With a suitable and constant degree of exhaustion, if the kathode is placed as shown in full lines in Fig. 1, X-rays of very high penetrative value are produced, while the small movement of about ·3 inch required to place it in the position indicated by the dotted lines, will suffice to reduce the penetrative value of the rays almost to nothing. Between these two extremes every grade of penetrative value is readily obtained by simply altering the position of the kathode between its limits of travel. If the tube be used in a horizontal position, this can easily be done by merely tapping it at one end or the other, without removing it from its support, and the anti-kathode being a fixture, the point of origin of the X-rays remains always in the same position. In this manner, with a single tube, and without alteration to the vacuum, X-rays of any desired penetrative value can readily be obtained, while at the same time it is possible to compensate for the uncontrollable variations in vacuum that are found to occur in practice, and thus to maintain the penetrative value of the rays at any desired degree.

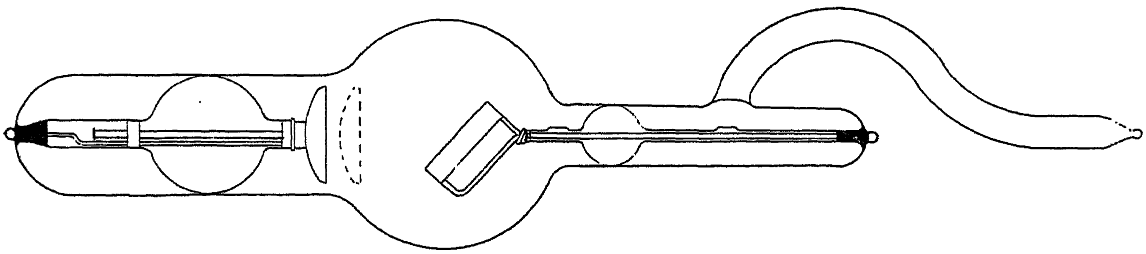

FIG. 1.

The effect is evidently due to changes in the electrical resistance of the tube, which, as measured by the alternative spark in air, is much highest when the kathode is in the position shown in full lines, *i.e.* that which gives rays of the greatest penetration, and appears to be closely connected with the proximity of the kathode to the glass, which is greatest in the position just mentioned.

This factor is evidently so important that it much more than neutralises the effect of the alteration to the distance between kathode and anti-kathode, which, as the writer has previously shown, has the result of increasing the penetrative value of the rays, and also the resistance of the tube, the nearer these two electrodes are together.

In order to obviate the overheating of the anti-kathode, which is a considerable source of trouble in all X-ray tubes when much electrical power is employed, the writer finds it convenient to mount the ordinary small disc of platinum upon a considerably larger and thicker disc of aluminium, say about 1 inch in diameter and ·25 inch in thickness, the platinum being tightly wedged and riveted in a shallow circular depression turned out of one face of the aluminium disc. Owing to the considerable radiating surface of the aluminium, and its considerable mass, this arrangement prevents the platinum from attaining an excessive temperature. In addition, the platinum having only one surface exposed, the tubes do not blacken so quickly.

Boomerangs without Twist.

IN your issue of May 13 (p. 46), a writer mentions some Australasian boomerangs as thrown *not to return* (if I have rightly understood him). I had not heard of these before, but in British India at least one race, the Kolis of Northern Gujarat, have the like. These are invariably of "fish" section, varying in weight, curve, and material; but the commonest and most efficient sort is of "Babul" wood (*Acacia arabica*), with the natural curve of the heart of the wood, something like that of an old-fashioned genuine Turkish sabre, rather a "knee" than any regular geometric curve.

They are used with great effect on ground-game; much less, of course, on birds. In one case an old and feeble man, threatened by a swordsman, cut the assailant's shins across with his boomerang at about ten paces, and *brought him down*. Before the astonished thief could rise, the now unarmed old man had disarmed and literally taken him captive.

I tried the case myself, gave the swordsman two years, and the boomerang man much honour. Certain people called *Maravars*, in the south of the Madras Presidency, are said to have similar boomerangs; but I have not seen them.

Many Indian races throw straight sticks at game habitually, and even in a city riot the thrown sticks are often more dangerous than those in hand (bar iron-bound clubs). But their practice is not scientific, like boomerang-throwing.

Scorpion carrying Flower.

ONE evening last February, while sitting in the verandah of my house at Aden, my attention was drawn to an object advancing across the floor, which seemed to be some peculiar leaf insect or phasma. On looking at it closer I saw it to be a scorpion (identified by Mr. Pocock from my description as *Parabuthus liosoma*), which was holding over its back by one claw a large blossom of *Poinciana regia*, known in Aden as the white-gold mohur tree. Its tail, curled over its back, further assisted in retaining the flower in position. The nearest tree from which it could have obtained it was at least 30 feet away, and to bring it the scorpion must have carried it over a low stone parapet and up two or three steps, so that intention seems to be proved. What that intention was it is hard to define. Hardly for concealment, for the size of the flower made it more conspicuous; besides, it was night. If it was the lamp-light it wanted to avoid, it is necessary to assume that, finding the light too strong, it went back to get the flower. It could hardly be as food, for scorpions are not known to live on vegetable substances; nor, as far as I know, do they construct nests. I regret that I did not allow the creature to reach its destination, and so ascertain its intention; but, unfortunately, I gave in to my first impulse and crushed it. My wife suggested that perhaps it was going to a wedding, but this explanation is more poetical than scientific.

Some of your readers may be able to throw a little light on this curious instance; but Mr. Pocock, of the British Museum, to whom I related the above, said he had never heard of a similar case.

A. NEWNHAM.

The Utility of Specific Characters.

MR. COCKERELL asks whether it is possible to explain right-handedness, the dextral or sinistral coil of snail-shells, and similar features as having any utility to the species, and he then speaks of

the advantages of uniformity. In the case of right-handedness it is obvious that these advantages must be great, as various tools and machines are made in conformity with the fact that nearly all persons use their hands alike; screws, for instance, having to be driven in by the rotation outward of the right hand. A left-handed man would naturally turn his wrist outwards to the left, and therefore the driving of an ordinary screw by turning the hand inward would be difficult and awkward.

In any community where there existed some left-handed men, and a building had to be erected, they would be found to be inferior workmen, and remain behind in the struggle for existence.

I understand Mr. Cockerell to say that in the case of spiral shells there may be natural environments tending to favour uniformity of shape and prolonged existence, just as in man these environments are artificial, but at the same time beneficial and tending to the same end. SAMUEL WILKS.

Grosvenor-street, May 19.

Luminous Phenomena observed on Mountains.

CONCERNING the letter of Mr. C. G. Cash, on "luminous phenomena observed on mountains," in your number of May 13 (p. 31), I do not doubt you will be informed by many readers of NATURE that they are evidently, and undoubtedly, due to St. Elmo's fire. J. M. PERNTER.

Innsbruck, University Observatory, May 21.

The Effect of Wind and Atmospheric Pressure on the Tides.

THE problem of the effect of wind and atmospheric pressure on the tides has received repeated and considerable attention from scientific as well as from practical men. Especially for the latter, *e.g.* sea captains and pilots, an acquaintance with the effects produced is of considerable importance.

The efforts and the money which all civilised nations employ in obtaining good tide-tables, prove that these are of utmost usefulness and value to navigation; and we need not be astonished at this, when we think of the necessity of a swift and safe course, especially in international trade.

The calculations of the tides in the tide-tables are principally based on astronomical influences; they indicate time and height of the tide, which may be expected from the relative position of sun, moon and earth, and generally refer to normal meteorological conditions.

In reality, those conditions differ from the normal state. Wind and atmospheric pressure are continually changing, and cause the time and the height of tide to vary in different degrees from the normal value indicated in the tide-tables.

Navigation has an interest in exact tide-tables, and, in the same way, the pilots and sea captains wish to be able to calculate the extent to which the depth of the water will be affected by meteorological influences, because it may depend on these, if it will be possible to cross a bar or shoal in a tidal river, or enter into the mouth of a tidal harbour.

So far there does not exist a formula, which allows the calculation of the correction to add to the data of the tide-tables, if the force and direction of wind and the indication of the barometer are known.

While in Germany considerable attention to the effect of wind on the tides has been paid by Hugo Lentz, Prof. Möller, Prof. Bübendey, and others, French scientific men have principally given their attention to the effect of atmospheric pressure. In the "Annuaire des marées des Côtes de France" a table is to be found, according to which a rise of one millimetre in the barometer causes a depression of the tide of 13 millimetres. The same correction can be used for all the harbours, and the seamen are advised to apply this correction. It can, however, be neglected for barometrical indications lower than the mean position, viz. 760 millimetres.

A civil engineer, E. Engelenburg, tried to calculate separately the effects of wind and atmospheric pressure for Flushing, in his article published in *De Ingenieur* (a Dutch weekly paper), No. 39, 1891. Unfortunately the records he used were not sufficient to afford a definite solution of the problem. Nevertheless, his study remains a very interesting addition to the literature on this subject.

All these investigations, however, have not led to any suitable formula by which the corrections for wind and pressure might be calculated. No wonder, therefore, that in England, the navigation-country *par excellence*, particular consideration has been paid to the said subject.

Many elaborate investigations thereon have been made by Mr. W. H. Wheeler, of Boston, who communicated the results of his study at the meeting of the British Association at Ipswich, in 1895.

Mr. Wheeler's address gave rise to the appointment of a Committee, consisting of Prof. Vernon-Harcourt, Prof. Unwin, Mr. Deacon, and Mr. Wheeler (Secretary), in order to investigate this subject, especially for the practical purpose of ascertaining whether the records of the wind and atmospheric pressure, as obtained by an observer at any particular port, might afford a trustworthy guide to pilots and mariners as to the variations to be expected in the height of the tides, from those ascertained by calculations and given in the tide-tables.

Information was asked from authorities of all the principal ports in Great Britain, and also from the Hydrographic Departments of the principal maritime ports in other countries.

The tidal records of five English ports, viz. Liverpool, Sheerness, Portsmouth, Hull and Boston, were selected for a careful examination. The results of these investigations have been presented in a report of the said Committee, drawn up by the Secretary.

In general the results obtained, both those relating to the effect of atmospheric pressure and those relating to the effect of wind, are not very satisfactory.

Nevertheless, the summary of the report contains a useful table giving the increase or decrease of tide for different forces of wind (3° to 10° Beaufort scale) per foot rise of tide.

The reason why the results are so little satisfactory, seems to me due to the method of investigation employed.

In analysing the effects of atmospheric pressure, a mistake was made by not sufficiently eliminating the effect of the wind. The latter being predominant, the effect of pressure could not be made clearly visible. Concerning the effect of wind, the principal cause of failure, I believe, is to be found in an erroneous working hypothesis, and in a wrong consideration of the influence of wind on the sea-level.

The hypothesis was, that wind blowing in the direction of the tide increases the range of tide; the high water being raised and the ebb being lowered, whilst wind blowing in a direction opposite to the tide has the contrary effect.

Considered from that standpoint the observations were separated according to the circumstance, whether the wind was blowing in the direction of the tide or contrary to it; and the results were drawn up in such a way as to show the amount of the raising or depressing of the tide, caused by the same force of wind at different ports, proportional to the mean rise of tide at those ports.

These considerations are contrary to the facts mentioned in Hugo Lentz's work, and also to the observations of the Dutch engineers on the coasts of Holland.

Those facts and observations show everywhere, that high and low water both are raised or depressed by wind, so that the range of tide is not considerably affected. They also show that the raising or depressing are not dependent on the range of tide, but depend to a great extent on the form of the coast-line, and especially on the depth of water; the effect increasing when the water is shallow.

Another point of difference is, that the most important influence is not felt when the wind is blowing in, or opposite to, the direction of the tide—as was supposed by the Committee—but, on the contrary, when the wind is blowing at right angles to the coast-line, *e.g.* perpendicular to the direction of the tide.

Hence the arrangement of the observations in the way adopted by the Committee could not but have the result that the raising and depressing of the tides partially neutralised each other.

The reasons just mentioned cause the table, according to which the variations due to wind is given per foot rise of tide, to be erroneous in principle, because the variation caused by wind is not proportional to the range of tide.

Trustworthy results can only be obtained if exact tide-tables are at our disposal; if the calculated data are compared with the observations, and the variations are arranged according to the simultaneous direction and force of the wind, and the atmospheric pressure; and last, not least, if the results are carefully arranged in such a way that each effect comes forth unaffected by the other. This principle is applied to the height and to the time of the tide on the Holland coast.

In order to get a thorough check, the calculations are made independent of each other for five series of observations as to the height, and for three series as to the time of the tide. A comparison of the results will show what degree of exactness can be obtained, and how far the obtained results can be trusted.

The said series contain—

I. (1) The height of high water at Ymuiden in 1895
(2) ,, ,, ,, ,, 1896
(3) ,, low ,, ,, 1895
(4) ,, ,, ,, ,, 1896
(5) ,, high ,, Hoek van Holland 1896

and

II. (1) The time of high water at Ymuiden in 1895
(2) ,, ,, ,, 1896
(3) ,, ,, Hoek van Holland 1896

The importance of checking is further increased because of the different methods of wind-observation.

At Hoek van Holland the indications of a self-registering apparatus were used, which gave the force in kilogrammes (kg.) per square metre. (1 kg. per square metre) = 0·205 lb. per square foot.)

At Ymuiden the direction and force were noted at 8 a.m. and 4 p.m.; the force was estimated by a scale of 6 degrees, the signification of these being as follows:—

Ymuiden scale	Signification	Equal to: Degrees of Beaufort scale	Pressure in kg. per square metre	Velocity in metres per second (1 m. = 1·09 yard = 3·28 feet).
1	Gentle breeze	1·9	4	5·7
2	Fresh ,,	3·3	9	8·5
3	Strong ,,	4·9	18	12·0
4	Gale	7·3	45	19·0
5	Heavy gale	—	—	—

The tidal observation has in each case been combined with the preceding meteorological observation; thus the latter, on an average, fell six hours before the moment of tidal observation.

This combination is not illogical. A special investigation at Hoek van Holland, concerning the question how much time a certain wind preceded its observed effect on the tide, in order to find the limits of this precedence, showed that the average effect on the height of tide followed the cause after a minimum of five hours (out of 17 observations), and a maximum of 6 hours (60 observations); and on the time of high water after a minimum of 4 hours (13 observations) and a maximum of 7 hours (33 observations).

The calculations for finding the effect of wind and atmospheric pressure have been made as follows.

The variations between observation and prediction (those for the height of tide after a proper correction concerning the annual variation of the height of half-tide) were arranged in groups. Each group contained the observations at a definite direction of the wind and a definite force; *e.g.* all the observations during N. wind and a force = 1° Ymuiden scale, were combined to a group N 1.

Considering that each group corresponds to a definite influence of wind, it is evident that the reciprocal differences of the variations, united in that one group, are caused by differences in atmospheric pressure.

A second supposition was, that the effect of atmospheric pressure in every group was proportional to the difference of the barometer from its normal value of 76 centimetres mercury.

Let, therefore, the wind-effect for a certain wind-group and normal barometer be x . . .

The rise of 1 centimetre barometric pressure corresponding to a depression of the sea-level of y centimetres . . .

The value of a variation $= v$ . . .

The observed barometric pressure $= 76 + b$ centimetres, then we have

$$x + by = v.$$

We have, therefore, in one group containing n observations, n equations with two unknown quantities x and y, out of which the values of x and y can be solved. This method has been applied to the groups containing ten or more variations.

The values of y thus calculated, with consideration of the number of the observations, served to deduce the effect of the directions of the wind on the value of y; this known, the groups containing less than ten variations were submitted to a correction according to the calculated value of y, and so the real value of x was obtained.

These values of x now served to deduce the following quantities:—

(1) The effect of absolute calm.
(2) ,, ,, the force of wind.
(3) ,, ,, the direction of wind.

As is known, the level of the sea at absolute calm differs from the mean annual level, because the latter is influenced by the prevailing winds.

In calculating the effect of wind the supposition was made, that for every direction the effect of definite forces is always expressed by the same proportion—*e.g.* the effect of a force 3 being double that of force 2; this proportion remaining the same at all directions of the wind.

The calculations made according to these principles showed that the effect of wind and atmospheric pressure on the tides can be represented by the following formula:—

$$C = (KR - a) + R_b(B - 76·0),$$

in which

C is the correction in centimetres to be applied to the predicted height of high, as well as low water.

K is a coefficient depending on the force of wind.

R is a coefficient depending on the direction of wind.

$-a$ is the correction which should be applied in the case of absolute calm (when K = 0).

R_b is a coefficient depending on the direction of wind, although relative to atmospheric pressure.

B is the atmospheric pressure in centimetres mercury.

In order to examine the results obtained by calculating the independent series of observations, I give those *in extenso*. They have reference to conditions which have, in general, similarity enough to allow the comparison, as the following results will prove.

I. Value of K.

Force of wind according to: Estimation in degrees of the Ymuiden scale	Pressure in kg. per m².	Calculated values of K at Ymuiden: High water 1895	High water 1896	Low water 1895	Low water 1896	Mean of the 4 values	Pressure of wind registered at Hoek van Holland, kg. per m². ,, 1896 Ymuiden ...	−12	−14	−11	−9	−8	−6	−5	−5	−4	−4	−4	−6	−7	−9	−12	−11
High water, 1896—Hoek van Holland	−13	−14	−15	−13	−10	−10	−12	−14	−12	−9	−9	−13	−16	−17	−12	−11

In calculating the effect of wind and atmospheric pressure on the time of high water at Ymuiden in 1895 and 1896, and at Hoek van Holland in 1896, exactly the same method has been followed.

The formula by which this effect can be expressed, is the following:—

$$C_r = KR + R_b(B - 76\cdot0).$$

C_r means the correction in minutes to be applied to the predicted time. For the rest the form of the formula is in every way equal to that for the height, except the disappearing of the term a. At absolute calm the mean time of high water, therefore, will not differ from the normal. The sign + signifies that the observed time of high water is later than the predicted, the propagation of the tide being retarded.

The following tables again give an idea of the results and the obtained degree of exactitude:—

I. Value of K.

Force of wind in degrees of the Ymuiden scale	Velocity of wind in m per second	Calculated values of K at Ymuiden: High water 1895	High water 1896	Mean value	Pressure of wind registered at Hoek van Holland, kg. per m²	Mean value	Corresponding velocity of wind in m. per second	Calculated value of K at Hoek van Holland, high water 1896
1	5·7	3	6	4^{6}	0	0	2	1
2	8·5	6	5	5^{9}	0−5	3	4·9	4·5
3	12·0	9	9	8^{8}	5−10	7	7·5	7
					10−20	14	10·6	10
					20−30	24	13·9	13
					30−50	38	17·4	20

As an explanation, it may be mentioned that the velocity of wind being v metres per second, the pressure can be represented by $k = \frac{1}{8}v^2$ (k being expressed in kg. per m²); and the pressure k being known the velocity $v = \sqrt{8k}$.

II. Value of R.

Direction of wind	N.	N.N.E.	N.E.	E.N.E.	E.	E.S.E.	S.E.	S.S.E.	S.	S.S.W.	S.W.	W.S.W	W.	W.N.W	N.W	N.N.W
Ymuiden, 1895	$0·4^{5}$	1·1	1·6	0·8	−0·4	−1·2	−1·1	−1·0	−1·3	−1·1	−0·9	−0·7	−0·2	0·1	0·3	$0·4^{5}$

Hoek van Holland, 1896	1·4	1·6	1·1	0·6	0·0	−0·5	−0·7	−1·5	−1·8	−1·4	−1·0	−0·7	−0·5	0·1	0·5	0·9

III. Value of R_b.

Direction of wind	N.	N.N.E.	N.E.	E.N.E.	E.	E S.E.	S.E.	S.S.E.	S.	S.S.W.	S.W.	W.S.W	W.	W.N.W	N.W	N.N.W
Ymuiden, 1895	1	−1	0	3	4	3	4	5	4	3	3^{5}	4^{5}	7	8	6	2
,, 1896	2	2	1	3	5	6	5	4	4	6	7	6	5	3	−1	0
Hoek van Holland, 1896	−2	−3	1	3	4	5	5	6	7	7	6	5	6	7	5	2

The given data may serve to show the value of the results.

We see that the correction for the height of high water, as well as of low water, at Ymuiden and Hoek van Holland, can be expressed by one formula with a sufficient degree of exactitude for practical use.

Herewith the proof is given that the wind and atmospheric pressure do not considerably change the range of tide, but affect the high and the low water in the same way, both being raised or depressed.

The value of a at low water seems rather larger than at high water; thus on an average the absolute calm-level at low water is 5 centimetres lower than the mean low water, and at high water 2 centimetres lower than the normal. In practice this difference of 3 centimetres may fairly be neglected; for the study of the phenomena, however, they are important, because they show that the raising of the level, caused on the Holland coast by the prevailing western winds, is rather more considerable at low water than at high water. The reason of this is the greater depth of water at high water-level.

The tables show very clearly that the influence of atmospheric pressure on the height of the tides is not the same for the different directions of the wind, but is the greatest during northern winds, the feeblest during southern winds; the proportion often being much more considerable than we might expect from the proportion of the densities of mercury and sea-water.

I think it probable that in this proportional factor, the character of wind is comprehended—that is to say, that at a certain atmospheric pressure the same observed wind may be more local than at another barometric pressure; in the latter case the wind, for instance, reigning over a more considerable part of the North Sea, and thus having a greater effect on the height of the sea-level.

Very remarkable is the evident and regular influence of atmospheric pressure on the time of high water, which at first consideration one would not expect. High barometer retards the time of high water.

The values of R show clearly that the sea winds raise the level of the sea, and off-shore winds cause a depression. North and south winds act as sea winds; the neutral line lies N.N.E. and S.S.E. The greatest rise is more considerable than the greatest depression, the former being caused by W.–W.N.W. wind, the latter by E.–E.S.E. wind.

The effect of wind on the time of high water is not in phase with that on height, but differs about 90° with it.

The tables indicate that southern winds, which have the same direction as the tidal wave, advance the moment of high water, whilst northern winds retard this moment. The most important retardation is observed during N.N.E.–N.E. wind; the most important advance during southern winds; the neutral line is between E.N.E. and E. and between W. and W.N.W.

The most remarkable result, brought out with surprising clearness, seems to have the character of a general law of nature (which, however, should be affirmed with perfect evidence by comparing the obtained results with those on other points observation), and is the following:—

That the raising or depressing is proportional to the pressure of wind, and that the advance or retardation in time is proportional to the velocity of wind.

It would be highly interesting if the same kind of investigation could be applied to the English North Sea coast, in order to see whether the influence of wind, as found for the Holland coast, is local, and therefore opposite to the results to be obtained at the English side; or if the results are the same, thereby indicating the influence to dominate the whole North Sea.

A special investigation as to whether a wind, continually blowing, increases or decreases the effect on the high water-level, did not give a definite rule. In general there seemed little difference in height between the first and the second high water for the same conditions of wind.

Strong off-shore winds seem to influence the second, and, principally the third and following high water-tide less than the first; so that the long duration seems to weaken the effect of off-shore winds.

Preceding formulæ now permit us to give a formula for practical use. This formula is:

(1) For the height of high water and low water at Ymuiden and Hoek van Holland,

$$C = KR - 3 - R_b(B - 76{\cdot}0),$$

expressed in centimetres.

(2) For the time of high water at Ymuiden and Hoek van Holland,

$$C_\tau = K_\tau R_\tau + R_{b\tau}(B - 76{\cdot}0),$$

expressed in minutes.

These formulæ give, as for the sign, the correction to be applied to the height, and the time predicted in the tide-tables.

The value of the coefficients are given in the following tables:—

Direction of wind		N.	N.N.E.	N.E.	E.N.E.	E.	E.S.E.	S.E.	S.S.E.	S.	S.S.W.	S.W.	W.S.W.	W.	W.N.W.	N.W.	N.N.W.
Values of	R ...	0·6	0	−0·7	−1·0	−1·3	−1·2	−0·8	−0·1	0·4	0·6	0·9	1·2	1·6	1·5	1·3	0·9
	R_b ...	12	11	10	9	7	6	7	8	8	6	6	8	10	12	14	13
	R_τ ...	1·1	1·4	1·3	0·6	−0·2	−0·8	−1·0	−1·2	−1·3	−1·1	−0·8	−0·6	−0·3	0·2	0·6	0·9
	$R_{b\tau}$ ...	0	0	1	3	4	5	5	5	5	5	5	5	6	6	3	1

The way in which the values of K and K_τ are to be chosen, depend on the way of observing the force of the wind. The mentioned relation between pressure, velocity of the wind, and the value of K and K_τ permits the choice of the proper value of the latter, pressure or velocity of wind being given.

If the force is estimated in degrees of the Beaufort scale, as is usual among mariners, we may choose K and K_τ according to the following table:—

Degrees of Beaufort scale	K=	K_τ=
0	0·4	1·5
1	2	3
2	6	4·5
3	10	6·5
4	16	8
5	25	10
6	36	12
7	50	15
8	70	18
9	90	21
10	110	25

The mean age of the effect of wind and atmospheric pressure in the calculation being considered as six hours, which is not far from the truth, we may consider that the prediction of the next high water in general ought to be corrected with the observation of wind and barometer at about the preceding low water; a case which will often occur in practice, when vessels wait for the rising water to enter into the harbour.

Suppose a sea captain approaches a harbour entrance, and wishes to determine the correction for the next high water, in order to apply it to the predicted height of the tide-table. He therefore observes direction and force of the wind, and also the state of the barometer, and finds, for instance:—

Direction	N.
Force	7 Beaufort.
Barometer	77·5 centimetres.

The values to be found in the given tables are:—

$$K = 50 \quad R = 0{\cdot}6 \quad R_b = 12.$$

The correction $C = (50 \times 0{\cdot}6) - 3 - 12(77{\cdot}5 - 76{\cdot}0) = 30 - 3 - 18 = 9$ centimetres.

Thus the high water-level will be raised by 9 centimetres above the predicted height of the tide-table.

It will be easy for English mariners to change these formulæ into others, expressed in feet and inches instead of in centimetres.

At the end of these deductions it will, perhaps, not be out

of place to state that the calculations give an approximation, and that no absolute reliance can be placed on the formula.

The effects to which the level of the sea is subject are so many and so varied, and there may be in operation agencies acting over a distant area which cannot be discovered by local observation, or which may have been in operation on previous days, that it will never be possible to give a correction of mathematical exactitude.

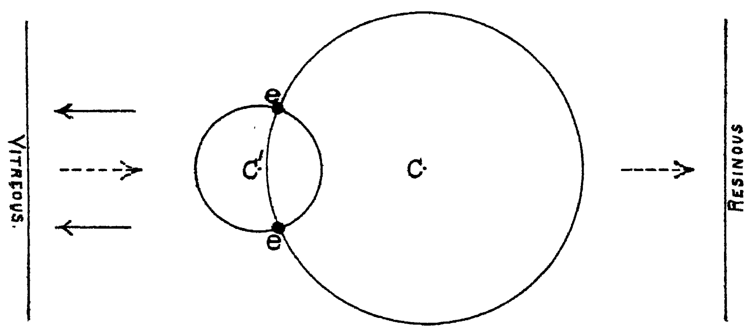
But every indication which approaches truth, and which increases our knowledge, is useful, and in this light the formulæ given should be considered. F. L. ORTT.

The Hague, Holland.

CONTACT ELECTRICITY AND ELECTROLYSIS ACCORDING TO FATHER BOSCOVICH.

YESTERDAY evening, in the Royal Institution, I spoke of an ideal one-fluid electricity subject to attractions of solid substance, to account for contact electricity of metals; and I said that before the end of our meeting I might speak of it further and might have to reverse the conventional language I was using as to positive and negative, and call resinous electricity positive, and vitreous negative. My allotted hour was woefully overpast, and half an hour more gone, before

CONFIGURATION BEFORE ACTION OF ELECTROLYTIC FORCE



ELECTROLYTIC FORCE SHOWN BY ARROWS.

I could return to the subject; and I felt bound to stop. What I wished to say may be said in the columns of NATURE in fewer words than I could have found, to make it intelligible, last night.

Varley's fundamental discovery of the kathode torrent, splendidly confirmed and extended by Crookes, seems to me to necessitate the conclusion that resinous electricity, not vitreous, is *the electric fluid*, if we are to have a one-fluid theory of electricity. Mathematical reasons, to which I can only refer without explanation at present, prove that if resinous electricity is a continuous homogeneous liquid, it must, in order to produce the phenomena of contact-electricity which you have seen this evening, be endowed with a cohesional quality such as that shown by water on a red-hot metal, or mercury on any solid other than a metal amalgamated by it. It is just conceivable, though it does not at present seem to me very probable, that this idea may deserve careful consideration. I leave it, however, for the present, and prefer to consider an atomic theory of electricity foreseen as worthy of thought by Faraday and Clerk Maxwell, very definitely proposed by Helmholtz in his last lecture to the Royal Institution, and largely accepted by present-day theoretical workers and teachers. Indeed, Faraday's law of electro-chemical equivalence seems to necessitate something atomic in electricity, and to justify the very modern name *electron*. The older, and at present even more popular, name *ion* given sixty years ago by Faraday, suggests a convenient modification of it, *electrion*, to denote an atom of resinous electricity. And now, adopting the essentials of Aepinus' theory, and dealing with it according to the doctrine of Father Boscovich, each atom of ponderable matter is an electron of vitreous electricity; which, with a neutralising electrion of resinous electricity close to it, produces a resulting force on every distant electron and electrion which varies inversely as the cube of the distance, and is in the direction determined according to the well-known requisite application of the parallelogram of forces.

In a solid metal the ponderable atoms must exert such other mutual forces, compounded with the electric forces, that the assemblage in equilibrium shall have the crystalline configuration, and the elasticity-moduluses, of the metal. The electrions must be perfectly mobile among the ponderable atoms, subject only to the condition that the electric attraction ceases to increase according to the inverse square of the distance and becomes zero (or, perhaps, strong repulsion) when the distance is diminished below some definite limit. For simplicity we may arbitrarily assume the following conditions:

(1) Each electrion is a point-atom of resinous electricity and repels every other electrion with a force varying inversely as the square of the distance between them.

(2) Each electrion is attracted by each ponderable atom with a force which varies inversely as the square of its distance from the centre of the ponderable atom when the distance exceeds a certain limit r and is zero when the distance is less than r.

(3) The shortest distance between two centres of ponderable atoms need not be limited to be $>2r$: it may be whatever we find convenient for the structure and properties to be realised. It will be $>2r$ in an insulating solid and $<2r$ in a conductor.

Two pieces of metal, M, M′, each constituted as I have now explained, will behave in respect to contact-electricity just as two pieces of metal behave in a perfect vacuum. For example, if $r>r'$, M will behave to M′ as zinc behaves to copper.

To illustrate electrolysis, consider an ideal case of a detached compound zinc-copper atom, composed of two single atoms with their centres at C, C′; and two electrions e, e which must, for equilibrium, be in the positions shown in the diagram, if r, r' be of such magnitudes as the radii of the circles showing the shortest distances to which C and C′ attract electrions. Let now electrified bodies at great distances (such as the vitreously and resinously electrified plates indicated in the diagram) act in the manner indicated by the dotted arrows relatively to the ponderable atoms, and the full arrows relatively to the electrions. The ponderable atom C will be drawn away to the right by the electric force on itself: and the ponderable atom C′ will be dragged away to the left by the two electrions overcoming the rightward force which itself experiences in virtue of the electric field. Lastly, to take a real case, the electrolysis of copper-sulphate, let C′ be the centre of an atom of copper in combination with oxysulphion (SO_4), not shown in the diagram; with, in all, six electrions. The copper atom C′ will be drawn away to the right, with no electrion attached to it: and the oxysulphion will be pushed and dragged to the left by the excess

of leftward electric forces on the six electrions above rightward electric forces on the five ponderable atoms.

KELVIN.

London, May 22.

NEW OBSERVATIONS ON THE LARVA OF THE COMMON EEL.[1]

IN our last note we announced that we had succeeded in following the transformation of *Leptocephalus brevirostris* into *Anguilla vulgaris*, and that the proof had been repeated by Prof. Ficalbi.

Our discovery was thus also confirmed by experiment. We were therefore ready to publish our work *in extenso*, and only regretted that we were unable to supply figures of the intermediate stages between the transparent (blind) Anguillina and the *Leptocephalus brevirostris* with its larval teeth still intact. The only example of this Leptocephalus obtained in a fit condition to survive and undergo its transformations in aquaria—that is to say, one uninjured and sufficiently advanced in its development (already deprived of a considerable proportion of its larval teeth), had already been made the subject of the above-named experiment.

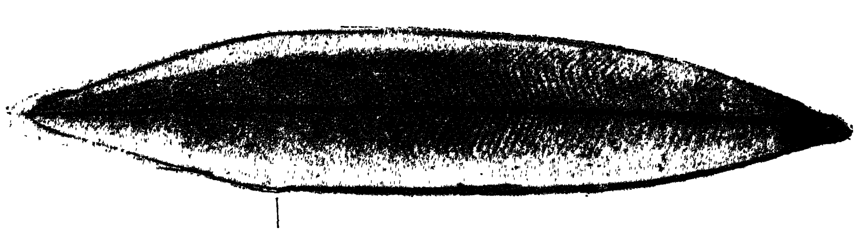


FIG. 1.—*Leptocephalus brevirostris*, with its larval teeth still intact (enlarged).

An unexpected chance has, however, fortunately procured us a *Leptocephalus brevirostris* which had acquired such characteristics as to convince anyone of the reality of the metamorphoses discovered by us. We think it desirable to give a preliminary notice of this precious specimen, by publishing an illustration of it by the side of that of another *Leptocephalus brevirostris* still having its larval teeth intact.

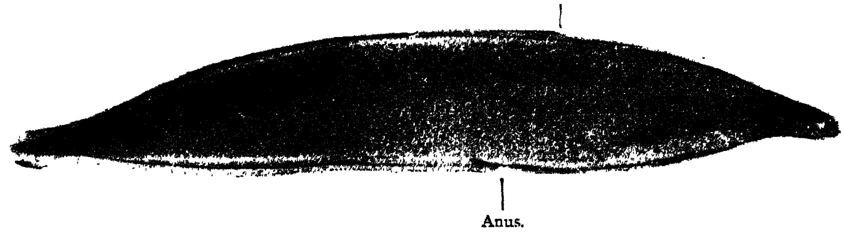

FIG. 2.—*L. brevirostris* captured by Dr. Silvestri (enlarged on the same scale as the preceding).

The present specimen was captured, last January, by Dr. Silvestri in the Straits of Messina.

Its total length is 71 mm. The anus is at about 29 mm. from the apex of the snout, the anterior extremity of the dorsal fin being about 25 mm. from the apex of the snout.

The head and the point of the tail have already noticeably acquired the known special characteristics of the eel.

The larval teeth have totally disappeared, while the distinctive ones seem still entirely absent.

It lacks all traces of pigment.

We will not proceed to further particulars, reserving them for our larger work.

[1] "Description of a *Leptocephalus brevirostris* in process of transformation into *Anguilla vulgaris*." Preliminary Note by G. B. Grassi and Dr. S. Calandruccio. Translated from the *Atti della Reale Accademia dei Lincei*, vol. vi. pp. 239–40, 1897.

TORONTO MEETING OF THE BRITISH ASSOCIATION.

II.—LOCAL ARRANGEMENTS.

THE material for the "Handbook of Canada," which is being prepared for the meeting, under the direction of the Publication Committee, is now complete, and there is every ground for believing that a large number of copies of the book will be ready about July 15, for distribution in England amongst the members of the Association who propose attending the Canadian meeting. The aim of the handbook is to give information on the Geography, Geology, Natural History, and Economic Resources of Canada. It will embrace chapters also on Public Administration and on the History of the Dominion. The Chairman of this Committee, Prof. Ramsay Wright, has succeeded in enlisting in the preparation of this work the aid of the most expert Canadian authorities, and there is no doubt that the publication, when it appears, will be regarded as a valuable guide to the Dominion.

In all probability the meeting will have a special distinction in the very large attendance of foreign men of science, an attendance larger than that of any previous meeting. The presence of the Presidents of a number of the leading American Universities, with a very large representation of the scientific members of their Faculties, will make the occasion one of very great interest to both nations. Out of this has again risen the suggestion to form an International Association for the Advancement of Science, and it has been pointed out that the nucleus of such an organisation can be formed at Toronto from the representative men from Europe and America in attendance here. The first meeting, according to this proposition, would be held in Paris in 1900.

His Excellency, the Governor-General of Canada, and Lady Aberdeen have accepted the invitation to be present at the meeting, and have arranged to hold a special Reception for the members of the Association, probably in the new Legislative Buildings, during the evening of August 19. His Excellency takes a deep interest in the coming meeting, and has expressed a wish to do what is possible to make it a success. The Lieutenant-Governor of Ontario, the Hon. G. A. Kirkpatrick, and Mrs. Kirkpatrick have also graciously offered to hold a reception for the members.

The Local Committee recognise how interesting the country about and near Toronto is from a scientific point of view and they have made arrangements whereby the

more important points can be seen under competent guidance. Prof. Coleman has undertaken to conduct a party interested in geology to examine the Glacial Beds of the Don Valley immediately east of Toronto. Here are found drift deposits more than 200 feet thick, resting directly on Silurian strata, and containing an abundance of fossils of extinct animal and vegetable forms which point to a climate in Glacial times considerably warmer than that which now obtains in the temperate zone. The change in the lake level brought about since the Glacial Era, is shown by the old shore-line of the ancient lake ("Iroquois Water") demonstrated in these deposits, which is 170 feet above the surface of the present Lake Ontario. At Scarboro' Heights, a few miles further east, the beds reach a thickness of 350 feet. The excursion to be conducted along the course of the Niagara River to the Falls will be under the guidance of two geologists who have made a special study of the region. The vertical walls of rock, 200 feet high, provide an admirable section of the Silurian strata of the region; and the marvellous history of the Falls and the great lakes and rivers of the St. Lawrence chain of waters will be illustrated on the spot.

The excursion to the Niagara region will be made on Saturday, August 21, and that to the Don Valley and Scarboro' Heights on August 23.

The Muskoka Lakes Association, formed of a large number of public-spirited Canadians, are making special arrangements for the excursion to the Muskoka Lake region. Some of the loveliest bits of scenery are to be found in this locality, and a stay of a couple of days (August 21–23) will constitute a very pleasant feature in the programme of the meeting. Many of the members who will take this excursion will be received as guests amongst the members of the Muskoka Lakes Association who have summer residences and camping-grounds on the islands. The Muskoka Lake Navigation Company have arranged for special trips of their steamers on the occasion. The railway fare from Toronto to Muskoka and return will probably be a nominal one.

It is generally recognised that this will be the last occasion for many years on which Canada will be honoured by the visit of so many scientific men, many of whom are veterans in the scientific progress of the nineteenth century, and it is felt that the opportunity should not be allowed to pass without attempting in some way to show the appreciation which Canadians have for the services rendered by them to science. It has in consequence been arranged to give a public banquet in honour of Lord Kelvin, Lord Lister, and Sir John Evans, the President-elect of the Association. The University of Toronto will, to judge from present indications, hold a special convocation during the meeting, at which, doubtless, a number of honorary degrees will be conferred.

The Cataract Construction Company of New York have very extensive electrical plant at Niagara Falls, which generates a large part of the current which supplies Buffalo and the neighbourhood. The Company has generously invited the members of the Association to inspect the plant, and it will arrange specially for the reception of the members who will accept the invitation.

The Director of the Harvard Astronomical Observatory has issued a special invitation to the members of the Association who are interested in astronomy, and who may be in Boston, to visit the Observatory.

The loss sustained by the American Association in the death of its President, Prof. E. D. Cope, is a severe one, and occurs at a critical time. Prof. Cope, it is understood, is to be succeeded by Prof. Theodore Gill, senior Vice-President of the Association, and there will consequently be no interruption in the arrangements for the session. The Council of the Association, at its recent meeting, resolved to extend to all the members of the British Association who will attend the Detroit meeting the privilege of honorary membership. It has also been proposed that, in the interval between the Toronto and the Detroit meetings, the members of the American Association take an excursion trip, the terminal point of which would be Toronto, and its final day August 18.

A. B. MACALLUM.

NOTES.

PROF. E. A. SCHÄFER, F.R.S., is unavoidably prevented from attending the forthcoming meeting of the British Association at Toronto, and in his absence the duties of General Secretary will be undertaken by Prof. W. C. Roberts-Austen, C.B., F.R.S., who will also deliver one of the evening discourses, on "Canada's Metals." The other evening discourse will be given by Prof. John Milne, F.R.S., on "Earthquakes and Volcanoes." The Council of the Association have resolved to nominate Mr. W. Crookes, F.R.S., as President for the meeting to be held at Bristol next year. We have already printed (March 25, p. 494) the list of the presidents of the various sections of the Toronto meeting.

AT the anniversary meeting of the Linnean Society, held on Monday, the gold medal of the Society was awarded to Dr. Jacob Georg Agardh, Emeritus Professor of Botany at the University of Lund, the distinguished algologist, and author of the "Species, Genera, et Ordines Algarum," which contains the first embodiment of the natural system applied to marine algæ as a whole. Greville, Harvey, and Kützing, no doubt, paved the way and made this task possible, but it nevertheless remains a monument of research and true systematic judgment. In 1872 he commenced a series of memoirs, "Till Algernes Systematik," which he completed in 1890; another great work, "Florideernes Morphologi," having appeared meanwhile in 1879. Ten years later he published his "Species Sargassorum Australiæ"; and in 1892, in his eightieth year, commenced a remarkable series of memoirs, the "Analecta Algologica," the completion of which he has happily achieved. In his unavoidable absence from England, the gold medal just awarded to him was received on his behalf by His Excellency the Minister for Sweden and Norway.

PROF. FELIX KLEIN, professor of mathematics in Göttingen University, has been elected a Correspondant in the Section of Géométrie of the Paris Academy of Sciences, in succession to the late Prof. Sylvester.

THE death of Sir Augustus Wollaston Franks, K.C.B., F.R.S., President of the Society of Antiquaries, will be deeply regretted by all archæologists. From an obituary notice in the *Times* we learn that Sir A. W. Franks was born in 1826, and was thus in his seventy-second year. He early developed the taste for mediæval archæology, upon which he afterwards became the leading authority. In 1849 his "Ornamental Glazing Quarries" was published, and among his other archæological works may be mentioned "Medallic Illustrations of British History," and an edition of Kemble's "Horæ Ferales," a volume which his additions converted into a standard work. He entered the British Museum as an assistant in 1851, and afterwards became Keeper of the Department of British and Mediæval Antiquities, and of Ethnography. Not only his own, but other sections of the Museum, bear witness to his catholic taste and great liberality. Upon his retirement from the Museum, he was placed on the Standing Committee, and took an active part in the work up to the time of his death. For some time he was Director of the Society of Antiquaries, and in 1891 he was elected President of the Society for a period of seven years. The Society as well as the Museum was

familiar with his liberality, and quite recently he presented to the Society some hundred volumes from his antiquarian library. His principal discovery in archæology was to separate the work of the age which produced what he called "Late Celtic" antiquities from that of the age which preceded and followed it. His persistency as a collector, moreover, managed to secure for the nation the best collection that exists of the remains of this period—a period which lies on the borderland between the prehistoric and historic periods in Britain, and about which antiquarian relics are our only means of knowledge. He was elected a Fellow of the Royal Society in 1874.

THE fund established by Mrs. Elizabeth Thompson, of Stamford, Connecticut, "for the advancement and prosecution of scientific research in its broadest sense," now amounts to 26,000 dols. (5200*l.*). We are informed that, as accumulated income will be available in November next, the trustees desire to receive applications for appropriations in aid of scientific work. This endowment is not for the benefit of any one department of science, but the trustees give the preference to those investigations, which cannot otherwise be provided for, which have for their object the advancement of human knowledge or the benefit of mankind in general, rather than to researches directed to the solution of questions of merely local importance. Applications for assistance from this fund, in order to receive consideration, must be accompanied by full information, especially in regard to the amount required, nature of the investigation proposed, conditions under which the research is to be prosecuted, manner in which the appropriation asked for is to be expended. All applications should reach, before November 1, 1897, the Secretary of the Board of Trustees, Dr. C. S. Minot, Harvard Medical School, Boston, Mass., U.S.A. Decided preference will be given to applications for small amounts, and grants exceeding 300 dols. will be made only under very exceptional circumstances. It appears from the list we have received, that of the seventy-one grants hitherto made, three have come to Great Britain, viz.: 150 dols. to Dr. Samuel Rideal, for investigations on the absorption of heat by odorous gases; 125 dols. to Mr. Edw. E. Prince, of St. Andrews, for researches on the development and morphology of the limbs of teleosts; and 250 dols. to Mr. Herbert Tomlinson, F.R.S., for researches on the effects of stress and strain on the physical properties of matter. Twenty-four of the remaining grants were given to men of science in America, twenty went to Germany, five to Switzerland, four to France, three to Belgium, three to Canada, and two to Italy.

DR. CHARLES W. DABNEY has been appointed "special agent in charge of scientific and statistical investigations" of the U.S. Department of Agriculture.

THE steamer *Bear* left Seattle on May 6 for the Arctic regions, having on board surveying parties of the United States Coast and Geodetic Survey, who have gone to survey the Pribyloff Islands.

THE *Times* correspondent at Copenhagen states that the "Carlsberg Fund" for scientific purposes has offered 150,000 kroner (about 8300*l.*) to the Danish scientific expedition to the east coast of Greenland, for the purpose of making a chart of the coast northwards to Angmagsalik.

AN "at home" was held by the President and Council of the Geological Society at the Society's Rooms in Burlington House, on Wednesday, May 19, when Mr. E. J. Garwood, who was a member of Sir Martin Conway's expedition to Spitzbergen, gave some account of the geology and glacial phenomena of that region.

THE annual report of the Brooklyn Institute shows steady growth in membership. Sir Archibald Geikie delivered before the Institute, on May 10, an illustrated lecture on the Hebrides. In the course of the lecture he remarked that he had never been able to understand the remarkable volcanic phenomena of these islands till his visit to the volcanic region of the western part of the United States eighteen years ago.

WE regret to have to include in this week's obituary the names of Mr. Martin L. Linell, assistant in the Department of Insects of the U.S. National Museum; Dr. C. A. L. Robertson, distinguished for his work in medico-psychology, and joint editor of the *Journal of Mental Science;* and Mr. John Ramsbottom, president of the Institution of Mechanical Engineers in 1870-71.

A SEVERE shock of earthquake, which lasted six or seven seconds, was experienced at Guadeloupe, West Indies, at 10.30 a.m. on April 30. It was most strongly felt at Pointe à Pitre, where the stone gable-end walls of over a hundred houses fell and crushed adjoining buildings. Several minor shocks were felt after the first disturbance. No premonitory sounds were heard.

THE report of the medical superintendents to the Metropolitan Asylums Board on the use of antitoxin in the treatment of diphtheria during the year 1896, has just been presented to the Board. The statistical results with regard to mortality are compared with those for 1894, the year immediately preceding the introduction of antitoxin, and the one in which the lowest mortality had been recorded up to that time; they show a marked improvement in all classes of cases, and especially in the severer ones. "We have had, in fact," the report states, "somewhat better results to record for 1896 than we had for 1895. . . . We have only to add that we still hold to the opinion that in the antitoxic serum we possess a remedy of distinctly—we would now say much—greater value in the treatment of diphtheria than any other with which we are acquainted."

THE conference of the members of the Institution of Civil Engineers was opened on Tuesday, under the Presidency of Mr. J. Wolfe Barry, C.B., F.R.S., President of the Institution. The President, in an address to the combined Sections, congratulated the members who had taken part in the designing and construction of the Blackwall Tunnel upon the successful completion of that work. He then gave an outline of the birth, parentage, and career of the Institution, which dates from 1818. At the conclusion of the address the work of the various Sections began. A conversazione was held on Tuesday evening, and was attended by some 1500 guests.

A GENERAL meeting of the members of the Federated Institution of Mining Engineers will be held in London, on Thursday (June 3) and Friday (June 4). The following are among the papers to be read:—"Presidential Address," by Mr. Lindsay Wood; "Machine Coal-mining in Iowa, U.S.A.," by Mr. H. Foster Bain; "Occurrence of Cinnabar in British Columbia, Canada," by Mr. W. Hamilton Merritt; "Notes on a Boring at Netherseal, Ashby-de-la-Zouch, Leicestershire," by Mr. G. J. Binns, with stratigraphical remarks by Mr. C. Fox-Strangways, and petrographical remarks by Mr. W. W. Watts; "The South Wales Anthracite Coal-field," by Mr. Morgan W. Davies; "The Lake Superior Iron Ore Region, with special reference to the Masabi Range," by Mr. Horace V. Winchell; "Gold in Nature," by Captain C. C. Longridge.

AN air-ship made a remarkable ascension from Nashville a few days ago, under the management of Mr. A. W. Barnard. The air-ship is a cylindrically-shaped silken bag, with rounding ends, and is 42 feet long and 16 feet wide, enclosed in a netting

which is attached to a beam. Ten feet below from this beam a saddle is suspended, with pedals like a bicycle, by which the four-bladed propeller, 10 feet in the rear of the aeronaut, is turned. Hydrogen gas was used to inflate the ship. After the ship had risen to the height of about 500 feet, the aeronaut turned completely around, to show that the propeller was effective. He continued rising till he was out of sight, and propelled the machine in a direction diagonally to the wind at a rate of ten or twelve miles an hour. After travelling fifteen miles, he returned to within four miles of the city; but he had to rise and fall so many times that his supply of gas became exhausted, and also one of the blades of his propeller broke, and he descended.

IT is stated in the *Times* that, in accordance with the recommendations of the Departmental Committee on Dogs, upon which the Board of Agriculture have already taken action in London, Lancashire, Yorkshire and the Midlands, a muzzling order will shortly be issued by the Irish Privy Council, and that, as the cases of rabies in Ireland are so widely scattered, the order will extend to the whole of that country. The Irish Privy Council intend also to issue an order relating to the importation of dogs, following closely upon the lines of the order already sanctioned for Great Britain, and referred to last week (p. 60). This combined action gives us reason for hope that rabies will some day be exterminated from our islands.

THE President of the Board of Trade has appointed a Committee, consisting of Sir Charles Hall, Q.C., K.C.M.G., M.P. (Chairman), Mr. James Alward, Mr. T. Gibson Bowles, M.P., Captain A. J. G. Chalmers, Rear-Admiral W. J. L. Wharton, C.B., F.R.S., Mr. Charles H. Wilson, M.P., to consider and report whether any, and, if so, what, alterations or additions are required in the regulations for preventing collisions at sea, as regards (1) the lights to be carried and exhibited, and the signals to be carried and used, by sailing ships, steam ships, and boats when engaged in fishing; (2) the expediency of requiring all ships to keep out of the way of steam ships when such ships are engaged in fishing; (3) the lights to be carried and exhibited by steam ships carrying pilots when engaged on their stations on pilotage duty.

A REMARKABLE glacial eruption occurred in the early months of the present year in the south of Iceland. A postman was crossing the sands of Skeidara, when suddenly he heard the glacier about two miles in front of him emit a long, groaning sound, and saw large masses of ice being hurled into the air from the glacier, immediately followed by a flood that descended upon the level sands, surging to and fro and carrying everything before it. He promptly turned his horse and rode away to the station of Nupsstad, on the western side of the glacier. Six days later he returned to the sands, and saw them as a belt of ice-waves extending from the glacier to the sea, a distance of at least twenty-five miles. The average breadth of this belt was about four miles. The height of the ice-floes or waves varied from 70 feet to 90 feet. It was impossible to cross this wall of ice except close by the foot of the glacier where the floes were far apart. On the other side of the ice-field were six newly-formed torrents rushing from the glacier. No damage to life or property was caused by this eruption, which is believed to have some connection with the severe earthquakes of last summer.

THE Report on Admiralty Surveys for the year 1896, by the Hydrographer, Rear-Admiral Wharton, C.B., F.R.S., has just been published as a Blue-book. Notwithstanding the progress of hydrography, and the constant employment of our own and foreign surveying vessels in many parts of the world, the requirements of modern steam navigation increase more rapidly than the advance of surveys. Every year newly-discovered rocks are reported, the number of which shows no signs of diminishing. During the year 1896 no less than 209 rocks and shoals which were dangerous to navigation were reported, and required to be notified to the public by notices to mariners. Among the many observations recorded in the report, we notice that the Goodwin Sands has continued its general movement towards the coast, and the area of drying sand has very largely increased since the last ten years, when only small parts of the bank were above low water. An account is given of the part taken by H.M.S. *Penguin* in the coral-boring expedition sent by the Royal Society to Funafuti Island, Ellice Group. Reference is made to the determination of the contour of the outer slopes of the atoll; and it is also pointed out that the soundings obtained by H.M. surveying ships during the past few years in the south-western part of the Pacific, on the course of their voyages from and to Australia, have very largely added to our knowledge of the conformation of the bottom, and valuable information has been collected for submarine telegraph cables, if required. H.M.S. *Waterwitch* was engaged at Tasmania and the Fiji Islands in 1896. A line of soundings run towards Norfolk Island, and from thence to Smoky Cape on the Australian coast, passing between the Elizabeth and Middleton reefs, disclosed the interesting fact that these reefs are not on the comparatively shallow ridge that connects New Zealand with Queensland, but rise from deep water on its flanks.

WE have received the Report of the Director of the Liverpool Observatory for the year 1896. In addition to the transit and other astronomical observations required by the Mersey Docks and Harbour Board, special attention has been given at this observatory to anemometrical observations, and various interesting papers have from time to time been published upon this subject, *e.g.* one on the velocity of the wind at Liverpool, by the late W. W. Rundell, based upon the data between 1852 and 1866. During the past year, Mr. W. E. Plummer has made a number of comparisons between the results obtained from a Dines' tube anemometer and the Robinson cup and Osler plate anemometer. The values of the first two have been recorded under eight principal points of the compass, and Mr. Plummer states that the result of the comparison is to some extent a surprise, as it was anticipated that the record of the Robinson instrument would be much too great, owing to the wind velocities being computed on the assumption, now generally regarded as erroneous, that the wind travelled at three times the velocity of the cups. The experiments, however, go to show that the appropriate factor to reduce the Robinson velocities to the Dines standard is not so low as was expected, and that the velocities published in past years have not been in error by so great an extent as 10 per cent. It is important to remember, however, that in such comparisons much depends not only upon a proper exposure, but upon the size of the cups and the length of the arms of the instrument employed.

DR. C. DIENER, of Vienna, contributes to the *Mittheilungen der K. K. geographischen Gesellschaft* in Vienna an exhaustive discussion of the bearing of geological research on the destruction of Sodom and Gomorrah. The Scriptural account of the catastrophe is examined in detail, and the descriptions of travellers are employed to work out a complete picture. From a comparison with similar more recent disturbances in various parts of the globe, Dr. Diener concludes that the cities of Pentapolis were overwhelmed by a violent earthquake affecting the whole basin of the Dead Sea, and following upon a series of minor undulatory movements. Masses of subterranean water were forced up to the surface, giving rise to extensive landslips, and

consequent inundation of large districts by the waters of the Dead Sea. At the same time the shock reopened the crater of a volcano on the eastern margin of the sea, and a violent eruption followed. This account, in Dr. Diener's opinion, best satisfies the geological conditions observed, and it may be admitted that it confirms the descriptive accuracy of the Biblical narrative.

THE new number of the *Zeitschrift der Gesellschaft für Erdkunde zu Berlin* contains two important memoirs—one by Dr. G. Schweinfurth on the stone quarries of the Mons Claudianus in the Eastern Egyptian Desert, and one by Dr. Hans Steffen on the relations of Patagonia to the frontiers of Argentina and Chili. Dr. Steffen's paper is illustrated by an excellent map of an almost unknown region.

DR. ARTHUR KEITH has reprinted his four papers on the Anthropoid Apes, published in *Natural Science* during last year, and has formed thereby a very useful index to the literature of these important animals. The books and papers on this subject are, as Dr. Keith observes, much more numerous than most people imagine, and are, moreover, scattered about in the publications of all parts of the world. New contributions to this engrossing subject cannot satisfactorily be made without a full knowledge of what has been previously written. This is, therefore, a most useful piece of work, for which naturalists should be duly grateful to the author.

THE work undertaken by Prof. Balfour Stewart, some years ago, in conjunction with Mr. W. W. Haldane Gee, and entitled, "Lessons in Elementary Practical Physics," was unfortunately interrupted by the death of Prof. Stewart, who only saw the completion of the second volume—that on Electricity and Magnetism. It has now been decided to complete the work by entrusting it to the hands of separate coadjutors; accordingly part 1 of volume iii. will appear immediately, containing a treatise on "Practical Acoustics," by Mr. C. L. Barnes. Part 2 of volume iii. will be a treatise on "Heat," by Mr. Haldane Gee; while the third part, completing the volume, will comprise "Optics."

AMONG noteworthy papers and other publications which have come under our notice during the past few days are the following:—*The Psychological Index*, No. 3, being a bibliography of the literature of psychology and cognate subjects for 1896, compiled by Mr. H. C. Warren and Mr. Livingston Farrand. This valuable index is a special issue of the *Psychological Review*.—Six fine portraits of the late Prof. E. D. Cope are given in the May number of the *American Naturalist*, together with several appreciative notices of his life and work.—A detailed obituary of the late Prof. Du Bois Reymond is contributed to the *Revue de l'Université de Bruxelles* by Prof. Paul Heger.—A catalogue of works on pure and applied mathematics, from the libraries of the late Prof. Cayley and Dr. Todhunter. These books and papers are offered for sale by Messrs. Macmillan and Bowes, and the list of them will interest many mathematicians and astronomers.—Dr. James Cappie contributes to the *Monist* (April) some suggestive considerations on the bearing of elementary physical principles on intercranial activities.

IN view of the growing use of acetylene for heating and illuminating purposes, it has become of importance to find out under what conditions the storage of the gas may become dangerous. Some time ago MM. Berthelot and Vieille found that an explosive decomposition could be set up in acetylene either by a fulminate cap or by a red-hot wire, provided that the pressure was above two atmospheres, this explosive decomposition taking place with extreme ease in the case of the liquefied gas. In the latter case, the effects of the decomposition were similar in character to those produced by high explosives. These results were only too rapidly confirmed by the fatal explosion in Paris of a cylinder of liquid acetylene. It has recently been found out that acetone is a good solvent for acetylene, and in the *Comptes rendus* (May 10) MM. Berthelot and Vieille give an account of their very complete experiments on this solution. After examining the relations between pressure and temperature for solutions of various strengths, they next studied the effects produced by exploding a small charge of mercury fulminate, and by a red-hot wire. It was found that solutions of acetylene in acetone, although still capable of explosion, were much safer than the gas alone, the pressure at which explosion began to be possible being raised from two to ten kilograms per square centimetre. For a given sized vessel the quantity of acetylene that can be safely stored is fifty times greater with acetone than without it.

THE additions to the Zoological Society's Gardens during the past week include two Common Marmosets (*Hapale jacchus*) from South-East Brazil, presented by Mr. W. A. Bromwich; a White-throated Capuchin (*Cebus hypoleucus*) from Central America, presented by Mr. T. H. Rudkin; two Bonnet Monkeys (*Macacus sinicus*) from India, presented by Mrs. Hardisty; a Cape Hunting Dog (*Lycaon pictus*) bred in Ireland, presented by the Royal Zoological Society of Ireland; a Vulpine Phalanger (*Trichosurus vulpecula*) from Australia, presented by Dr. J. Martin Kennedy; a Peregrine Falcon (*Falco peregrinus*), captured in the Red Sea, presented by Mr. J. Kilpatrick; an Alexandrine Parrakeet (*Palæornis alexandra*) from India, presented by Mrs. E. Hight; three Cocteau's Skinks (*Macroscincus cocteaui*) from the Island of Raza, Cape de Verde, presented by Mr. Boyd Alexander; an Antillean Boa (*Boa diviniloque*) from St. Lucia, presented by Captain Digby H. Barker; a West African Python (*Python sebæ*) from West Africa, presented by H.E. Colonel F. Cardew, C.M.G.; a Smooth-headed Capuchin (*Cebus monachus*, albino) from South-east Brazil; two Green Monkeys (*Cercopithecus callitrichus*) from West Africa, two Blue Penguins (*Eudyptula minor*) from New Zealand, deposited; two Wallabys (*Macropus*, sp. inc.), an Australian Pelican (*Pelecanus conspicillatus*) from Australia, purchased; a White-tailed Gnu (*Connochetes gnu*) from South Africa, received in exchange; a Japanese Deer (*Cervus sika*), a Patagonian Cavy (*Dolichotis patachonica*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE ORIGIN OF SOLAR AND STELLAR LIGHT.—We have received a small pamphlet of eight pages (including the preface and a supplement) entitled "The Explanation of the Origin of Solar and Stellar Light, and the minor phenomena connected therewith," written by Mr. M. R. Dissett, and published at the moderate (?) price of one shilling. The author of these pages expounds a theory of the universe in which the element of "temperature" plays no *rôle* whatever; in fact, he says "it requires only magnitude and distance sufficient for any non-luminous body to become a brilliant star." Indeed, he goes on to say, "the fact that all the heavenly bodies, without exception, the rarest gases as well as the most solid bodies, give light in proportion to their magnitude, density and distance, might long ago have suggested that their brilliancy must be due to some such principle and not to their being incandescent matter, a theory as puerile as it is unscientific." The "principle" alluded to in the extract, is none other than that by which the light "reflected by a comparatively dull body, such as a planet, becomes more intense as its apparent disc diminishes in increasing distance, till finally it becomes a brilliant star." Arguing from this, the author explains how our sun does not shine by his own light, but is non-luminous and reflects star light. In fact, he infers that every body in the heavens appears bright on this principle. One might be inclined to ask whence the original light, since every body seems to be capable only of

reflection, comes. This difficulty is also explained on this "principle," for it "accounts for how light itself is generated, for the forces that generate light . . . are everywhere at work, though the result may not be immediately apparent to our senses." As this "principle" seems to be capable of enlightening astronomical science on so many points, we think we have mentioned enough of them for the reader to imagine the rest.

THE NEBULA OF ORION.—Two publications of the observations of the nebula of Orion have recently come to hand, one relating to eye observations, and the other restricted to photographic work. The former of these forms part of the publications of the "Leander McCormick Observatory of the University of Virginia" (vol. i. part 7), and consists of the eye observations made by the Director, Mr. Ormond Stone. A minute comparison of the results obtained by this survey with those given in the second publication should no doubt prove of great interest. This latter work we owe to Dr. Scheiner; it forms the second part of the eleventh volume of the "Publicationen des Astrophysikalischen Observatoriums zu Potsdam." In this Dr. Scheiner has investigated the details of this nebula as registered by several photographs, and he had also, with the intention of tracing some relationship between the nebula and the stars in and around it, completed a rigorous measurement of the position of the stars on the photographic plates. The main result of the investigation shows that undoubtedly there is a relationship between the nebula and the neighbouring stars. This result is satisfactory in that it is just what we should expect on the meteoritic hypothesis, and further corroborates Mr. Isaac Roberts's recent work, which also indicated a close connection between stars and nebulæ.

THE PARALLAX OF 61^1 CYGNI.—Mr. Herman S. Davis contributes to the *Astronomical Journal*, No. 402, the results of his investigation of the parallax of 61^1 Cygni. In this work he has employed the nineteen negatives of this star taken, between the years 1871–74, by Mr. Rutherfurd. The methods of reduction by differences of distance of two stars, having approximately equal distances, and differing about 180° in position-angle, are here the same as were employed for the parallax of μ, θ and η Cassiopeiæ in previous investigations. In addition to measures of distance, those of angle have here been employed. Taking the means of the values given in the *Astronomical Journal*, that for measurement of distance is $+0''.3999 \pm 0''.0230$, and for measurement of position-angle $+0''.3326 \pm 0''.0189$. The resulting value for the mean relative parallax of this star is therefore $+0''.360 \pm 0''.0146$. Mr. Davis adds that a complete discussion of the measure of 61^1 Cygni will soon be published as Contribution No. 13 from the Observatory of Columbia College.

THE ROYAL SOCIETY CONVERSAZIONE.

THE first of the two conversazioni held annually at the Royal Society took place on Wednesday, May 19. The following is a list of the exhibits:—

Illustrations of the Dansac-Chassagne process of producing photographs in colour: Sir H. Trueman Wood.

Apparatus for ascertaining duration of explosion, pressure developed, and rate of cooling of products of combustion: Sir A. Noble, K.C.B., F.R.S. The recording instrument consists of a rotating drum on which two pencils mark (1) seconds, (2) the pressure in tons per square inch indicated by a specially designed manometer; the pressure pencil traces out a curve, from which can be deduced the approximate time of explosion, the pressure reached, and the rate at which the gases cool; a second instrument is attached, on which the pressures and seconds are indicated by small electro-magnets.

Stress effects produced by convective electric discharges: Mr. J. W. Swan, F.R.S.

Apparatus for the comparison of thermometers: Mr. W. Watson.

A powerful electrical influence machine: Mr. J. Wimshurst. The machine has 24 discs, each 3 feet in diameter; they are so arranged as to furnish three poles, one of which may be negatively charged, the other two poles positively charged, or at pleasure the reverse order may be followed; by this arrangement two separate streams of discharge may be in use at the same moment.

(1) Model of a Hertz wave transmission; (2) two kinematic models: Prof. Silvanus P. Thompson, F.R.S.

Graphic representation of the Rothamsted observations on the continuous growth of wheat: Dr. H. E. Armstrong, F.R.S.

Certain bones of the ancient Naquada race, exhibiting characters of morphological or pathological interest: Mr. E. Warren.

Restored skeleton of *Æpyornis Hildebrandi* (Burckhardt) from Madagascar. The skeleton exhibited is the *first* and almost complete skeleton of *Æpyornis Hildebrandi* hitherto obtained from Madagascar. *Nesopithecus Roberti* (Forsyth-Major), a fossil monkey of an entirely new genus, and other objects: Dr. C. I. Forsyth-Major. (The collection was made by means of grants from the fund administered by the Royal Society.)

Glacial phenomena of Cambrian or Pre-Cambrian age, from the Varanger Fjord, Norwegian Lapland: Mr. Aubrey Strahan.

Photographs of the moon taken with the new Thompson 26 in. photographic telescope, at the Royal Observatory, Greenwich: the Astronomer Royal.

Photographic Atlas of the Moon, published by the Observatory of Paris; executed by MM. Lœwy and Puiseux: the Library of the Royal Society.

(1) Photographs illustrating enhanced lines in the spectra of the chemical elements, and the importance of such lines in the spectra of the hotter stars. (2) Solar photographs, taken at Dehra Dun, India, showing a kite and a locust projected on the sun's disc. Forwarded by Mr. J. Eccles. (3) Photographs illustrating the spectroscopic results obtained by the Eclipse Expedition to Novaya Zemlya, August 1896. (4) Photographs illustrating preparations and arrangements for the observation of the total eclipse of the sun August 1896, at Kiö Island, Varanger Fjord, Norway: Mr. J. Norman Lockyer, C.B., F.R.S.

Experiments with kathode and X-rays: Mr. A. A. C. Swinton.

A selection of dried plants from Tibet, collected by Captain Deasy and Mr. Arnold Pike, Captain Wellby and Lieutenant Malcolm: the Director, Royal Gardens, Kew.

Photographs illustrating the micro-structure of alloys: Mr. J. E. Stead.

Some photographs of optical projections in space: Mr. Eric Stuart Bruce.

Apparatus showing the phase change of light reflected at a glass-silver surface: Mr. E. Edser and Mr. H. Stansfield. The apparatus exhibited is a modification of Michelson's differential refractometer, the interfering rays being reflected at the back surfaces of the end mirrors. On these surfaces are deposited silver films, one being wedge-shaped, with a horizontal streak rubbed off, and the other uniform. Where vertical bands cross from the glass-air to the glass-silver surface a lateral displacement is produced, which varies from zero at the thin end of the wedge to ⅜ of a band at the thick end. The direction of the displacement indicates a retardation.

Apparatus for micro-photography: Prof. Roberts-Austen, C.B., F.R.S. A microscope and camera is arranged for obtaining photographs of metals and alloys under high magnification. The illustrations show the mode of existence of carbon in steel, and include the diamond form of carbon. The magnifications vary from 500 to 1000 diameters.

Living specimens of *Proteus anguinus*, Laurenti: Mr. E. J. Bles.

A collection of British Medusæ: Mr. E. T. Browne.

(1) Experiments with highly-dilatable and nearly non-dilatable nickel steel; (2) diagrams of expansion; (3) compensated pendulum made of nickel steel: M. C. E. Guillaume, Bureau International des Poids et Mesures.

(1) Superficial colour changes of a silver-zinc alloy; (2) X-ray photographs of sodium-gold alloys: Mr. C. T. Heycock, F.R.S., and Mr. F. H. Neville.

(1) Improved hatchet planimeter; (2) the cyclesograph, an instrument for describing arcs of circles of large radius: Mr. E. K. Scott.

The diffraction kaleidoscope: Mr. C. P. Butler.

A mid-water tow-net: Dr. G. H. Fowler.

Rotating discs, showing subjective colour phenomena: Mr. Shelford Bidwell, F.R.S.

Demonstration of Zeeman's discovery of the broadening of

spectrum lines by the action of a magnetic field on the source of light: Prof. Oliver Lodge, F.R.S.

Commensalism amongst marine animals: the Marine Biological Association.

Experiments on the transmutation of sound vibrations: Mr. J. Gcold.

Examples of animal-forms peculiar to Lake Tanganyika: Mr. J. E. S. Moore.

The Tsetse fly and the parasite of Tsetse fly-disease, or Ngana: Dr. A. A. Kanthack, Mr. W. F. H. Blandford, and Mr. H. E. Durham.

(1) Egg of *Æpyornis maximus* (Grandidier), Madagascar; (2) egg of African ostrich for comparison of size; (3) photograph of a fossil frog (*Discoglossus Troscheli*, Meyer sp.) from the lignite (Miocene) of Rott, near Bonn, and sciagraph of a recent frog of the same genus (*Discoglossus pictus*, Otth), for comparison. By Messrs. James Green and James H. Gardiner: Dr. Woodward, F.R.S., on behalf of Mr. R. Damon.

Ceraterpeton Galvani, Huxley, coal measures, Kilkenny, Ireland: Dr. Woodward, F.R.S., for Mr. J. G. Robertson, of Dublin.

(1) Living specimens of the British Mymaridæ (egg parasites), terrestrial and aquatic; (2) mounted specimens of newly-discovered genera. Mounted specimens of newly-discovered male Prestwichia: Mr. F. Enock.

(1) Specimens of Lepidoptera altered by temperature experiments, and reared by the exhibitor; (2) some of the results of crossings carried out by the exhibitor: Dr. M. Standfuss, of Zürich.

Examples of alteration of insects by temperature applied in the pupal stage: Mr. F. Merrifield.

Some examples of geographical distribution among the micro-Lepidoptera, with specimens from different regions, and coloured maps: Lord Walsingham, F.R.S.

Blood corpuscles of some invertebrate animals. Digestive gland of *Ostrea*: Dr. C. A. MacMunn.

A rotating mirror, specially made to the order of exhibitor by the Cambridge Instrument Co.: Sir David Salomons, Bart.

A rowing indicator, giving continuous record: Mr. F. C. Atkinson.

A new pocket mercurial standard barometer: Prof. J. Norman Collie, F.R.S., and Captain H. H. P. Deasy.

An apparatus for investigating the influence of proximity of substances on voltaic action: Dr. Gore, F.R.S.

Micrometer for microscopic measurement of large objects. Manufactured by the Cambridge Scientific Instrument Co.: Prof. W. F. R. Weldon, F.R.S.

Earth thermometer. A simple apparatus for the determination of earth temperatures: Mr. E. H. Griffiths, F.R.S.

Experiments illustrating a new method of controlling the electric arc in its application to photo-micrography: Mr. T. A. B. Carver and Mr. J. E. Barnard.

Kamm's "Zerograph," or "Printing Telegraph System": Mr. L. Kamm.

New phototheodolite, designed by Mr. J. Bridges-Lee: Mr. Casella.

The following demonstrations, with experiments and lantern illustrations, took place in the meeting-room:—

Experimental demonstration of "some electric and mechanical analogues": Prof. W. E. Ayrton, F.R.S.

Lantern-slides from micro-photographs, illustrating nuclear division in animal and vegetable cells: Prof. J. B. Farmer. Slides were shown illustrating the process of fertilisation and segmentation of the egg in *Ascaris megalocephala*, and in *Fucus vesiculosus*.

INFLUENCE OF RÖNTGEN RAYS UPON ELECTRICAL CONDUCTIVITY.[1]

In a note read on March 1 in the Royal Society of Edinburgh, Lord Kelvin, Drs. Beattie, and Smolan treat of the influence of the Röntgen rays on the conductivity of air, paraffin, and glass (NATURE, vol. lv. pp. 498-99). After careful experiments, made with different potentials, they conclude that no perceptible increase of the conductivity of paraffin and glass is produced on them by the action of the X-rays. On the contrary, Messrs. J. J. Thomson and M'Clelland have thought, after their experiments, that paraffin and glass, submitted to the X-rays, increase conductivity. I had employed myself in the same question some time before, and I have explained the results of my researches in two notes presented to the Royal Academy of Naples on May 9 and July 4, 1896, and in a third note presented to the Royal Academy of the Lincei in Rome on June 6, 1896. This last note begins with the following words:—

"My first idea was to study whether the X-rays, crossing a dielectric, could render it conductor, so as to facilitate across it the discharge of an electrified body. In these researches of mine I employed, as a dielectric, some paraffin because, besides its being one of the best insulators, it is also very transparent to the X-rays."

The results set forth in those three notes may be thus shortly re-stated.

The discharge of a conductor in the air, provoked by the X-rays, seems to take place by convection or transport; so to say by an electric dance of the particles in the air, roused by radiation. Righi's experiments lead likewise to a similar interpretation.

The discharge of the conductor becomes slower when the surface exposed to air is diminished—that is to say, when a portion of it is covered with paraffin.

A conductor, loaded with electricity and narrowly surrounded by a wrapper of paraffin, loses, by a first action of the X-rays, a small part of its discharge, and in the following times, after having been freshly charged to its primitive force, it always loses less, so that at the third, fourth, or fifth experiment the discharge is imperceptible or next to nothing. Therefore paraffin, under the action of the X-rays, does not gain in conductivity.

India-rubber behaves almost in the same manner as paraffin.

If the conductor is surrounded first by air and further out by a tube of paraffin, the conductor excited by the X-rays discharges itself, at first rapidly enough; but, soon after, the discharge proceeds, to the last, very slowly. As usual, electricity, carried by air, soon loads the sides of the tube, and then disperses itself with difficulty.

Electricity, scattered from the body, submitted to the action of the rays, can join itself again on a tube of paraffin, or of insulated metals, surrounding the discharging body. This electricity, gathered up on a tube, can be directly observed with an electroscope provided with dry piles, and is found, as is to be expected, of the same nature as that of the body itself.

Insulating liquids (turpentine oil, vaseline, Venetian turpentine, and petroleum) were also examined by me, and they behaved almost in the same manner as paraffin. An electrified conductor submerged in one of these liquids (vaseline oil is the best of all), under the action of the X-rays, discharges itself at first rapidly, but soon after the discharge stops almost entirely.

Lastly, the conductive property of the gases, crossed by the X-rays, increases with their density, and may be ranged in the following order:—

Hydrogen, lighting gas, air, carbonic anhydride, and vapours of ether or carbonic sulphur.

The results, relative to the first four gases, agree with those already given by Righi.

[1] Experiments published May, June, July 1896, proving that solid and liquid insulators retain their insulating powers under the influence of the Röntgen rays. By Prof. Villari. Communicated by Lord Kelvin.

THE CHEMISTRY OF THE HOTTEST STARS.

At a discussion meeting of the Royal Society, held some two months ago, a paper was read by Mr. J. Norman Lockyer, C.B., F.R.S., under the above title. This has recently been published, and we reproduce the general conclusions.

(1) In a mixture of vapours at a particular temperature, a vapour which is not present in sufficient quantity to show all the lines of its spectrum will be represented by the lines which are longest in its spectrum at the particular temperature in question.

Only some of the short lines in metallic spectra represent the effects of high temperature.

(2) Some of the substances which have been investigated, including iron, calcium, and magnesium, have probably a definite spectrum, consisting of a few lines, which can only be completely produced at a temperature higher than any which is at present available in laboratory experiments. The lines constituting the new spectra are those which either only appear in the spark spectrum, or are lengthened in passing from the arc to the spark. Such lines are termed enhanced lines.

(3) In the case of iron, calcium, and magnesium, there are four distinct temperature steps which are marked by spectral changes: (*a*) the flame spectrum, (*b*) the arc spectrum, (*c*) the spark spectrum, (*d*) a spectrum consisting solely of those lines which are enhanced in passing from the arc to the spark.

(4) The order of temperature of certain stars, as determined from a comparison of the extensions of the continuous spectrum into the violet or ultra-violet, is precisely the same as that which follows from a comparison of the metallic spectra at the four stages of temperature.

(5) The variations of the metallic lines furnish the most convenient means of determining relative stellar temperatures, for the reason that photographs with special exposures are unnecessary.

(6) Having ascertained the relative temperature of a star in this way, and assuming that all the absorbing vapours are at the same temperature, the presence or absence of any other metallic substance can be determined by looking for the lines which are longest in its spectrum at that temperature. In the case of the hottest stars, the fourth stage spectrum must be the term of comparison.

(7) Accepting the new results with regard to the lines enhanced in the spark, several lines in the spectra of the hottest stars, for which no origins could previously be assigned, can now be ascribed to metallic substances at the fourth stage of temperature.

(8) The lines of the cleveite gases appear only in the hotter stars, as indicated by the extension of the continuous radiation into the ultra-violet. They increase in intensity with increased temperature in certain stars.

(9) The order of stellar temperatures, determined from the *increasing* intensity of the lines of the cleveite gases, is identical with that determined from the *decreasing* intensity of the metallic lines in the case of those stars which show both series of lines:

(10) Different substances are spectroscopically visible through different ranges of stellar temperatures. The hydrogen lines are visible in stars ranging in temperature from that of α Orionis to that of Bellatrix, while those of the cleveite gases do not appear below the temperature of α Cygni. The enhanced lines of calcium appear at temperatures as low as α Orionis, and persist, with reduced intensity, to the temperature of Bellatrix; those of iron do not appear at temperatures lower than that of α Cygni, and disappear altogether at the temperature of Bellatrix; while the enhanced line of magnesium appears at the temperature of α Cygni, and remains feebly visible at the temperature of Bellatrix.

(11) It follows, then, that the enhanced metallic lines may be absent from a stellar spectrum, either because the temperature is too low or too high.

(12) In the case of those stars which previous investigations have shown to be cooling, the metallic line phenomena are inverted. The enhanced lines first become visible, then the arc lines; while the enhanced lines disappear at a certain stage in the process of cooling the arc lines continue to become stronger.

(13) The lines of the cleveite gases show a similar inversion on the downward side of the temperature curve. Strongly represented in the hottest stars, they thin out very rapidly in cooling stars, and disappear before the arc lines have begun to show themselves.

(14) Utilising the iron lines as a method of bringing together stars of approximately equal temperature, it is found that at each stage the stars are divisible into two groups, which, in accordance with my previous work, correspond to increasing and decreasing temperatures respectively.

(15) As determined in this way, stars of increasing temperature differ from those of decreasing temperature at the same stage of heat: (1) in the greater continuous absorption in the violet or ultra-violet, (2) in the generally greater intensity and breadth of the metallic lines, (3) in the smaller thickness of the hydrogen lines, (4) in the greater thickness of the helium lines at those stages in which they are visible.

(16) These differences are all explained on the meteoritic hypothesis.

(17) There are stars, near and at the top of the curve, which cannot be arranged in order of temperature by the criteria referred to in (15), for the reason that the iron lines have disappeared, and the lines of hydrogen and cleveite gases show little variation.

(18) The arrangement of stars about the top of the curve will depend upon the conditioning of certain lines, at present of unknown origin; the necessary criteria, therefore, require further investigation.

(19) The known facts with regard to changes in the line spectrum of an element can be easily explained on the hypothesis of successive dissociations analogous to those observed in the case of undoubted compounds.

(20) Similarly, the differences in the lines representative of a metal such as iron in the spectra of sun-spots, prominences, chromosphere, or different stars, are explained by supposing that there are different molecular groupings at each stage of temperature.

(21) The change from a continuous spectrum to one consisting of flutings, and afterwards to one of lines, is now acknowledged to be due to the existence of different molecular combinations.

(22) The recent investigations of Humphreys and Möhler on the shifts produced in metallic lines, when the vapours are observed at different pressures, confirm my view that the line spectrum of a metal integrates for us the vibrations of several sets of molecules.

(23) It is argued that the existence of "series" of lines in the spectra of some chemical elements is another indication of molecular complexity, each series probably representing the vibrations of similar molecules.

(24) The behaviour of the magnesium lines in stellar spectra is ascribed by Dr. Scheiner to differences of temperature, in accordance with my experimental results of 1879.

(25) The experiments on the spectrum of mercury which have been made by Eder and Valenta have revealed variations which according to them favour the dissociation hypothesis.

(26) On various grounds, the view that the differences in stellar spectra represent fundamental differences of chemical composition is untenable. The fact that many stars which are widely separated in space give identical spectra, indicates that they not only contain the same "elements," but that the "elements" exist in the same proportions in all.

(27) On the non-dissociation hypothesis, the action of heat on the sun's chromosphere could not produce such a spectrum as that which we know to be associated with hotter stars, since the relative proportions of different vapours could not be changed. The only change which can be imagined to take place on this hypothesis is a reduction of intensity of all the lines due to reduced pressure.

(28) On the dissociation hypothesis, increased temperature would bring about fundamental changes in the spectrum due to molecular simplifications, and in this way the effect of an increase of temperature on the sun's chromosphere, as indicated by hotter stars, can be predicted, and receives a simple and sufficient explanation.

(29) The disappearance of the enhanced iron lines in the hottest stars, and the simultaneous intensification of the lines of hydrogen, helium, and gas X, bring us face to face with the fact that iron is a compound, into the ultimate formation of which one or all of these gases enters.

(30) The ultimate molecules of the chemical elements discussed in the present paper may be provisionally arranged in the following order of resistance to the effects of temperature:—

$$\left.\begin{matrix}\text{Gas X}\\ \text{He}\end{matrix}\right\}\text{ Doubtful which.}$$
H
Ca
Mg
Fe

(31) Each step in advance which has been made since 1873, has demonstrated more and more that there is really such a "celestial dissociation" going on as that which I then suggested.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The sixth Robert Boyle Lecture of the Junior Scientific Club will be delivered in the Examination Schools, on Tuesday, June 1, at 8.30, by Captain Abney, C.B., F.R.S., who has chosen for his subject "The Scientific Requirements of Colour Photography."

Mr. W. Garstang, Fellow and Lecturer of Lincoln College,

has been appointed Naturalist to the Marine Biological Association, Plymouth.

The Drapers' Company have asked Mr. Jackson, the University architect, to inquire whether, for the sum of 15,000*l*., a new building can be erected to accommodate the Radcliffe (Scientific) Library.

Before the end of the present term an election will be made to the Oxford Biological Scholarship at Naples. Candidates must be graduates of the University, and are requested to send their names to the Linacre Professor of Comparative Anatomy at the University Museum before the end of May.

An examination for Scholarship and Exhibition is announced to take place at Wadham College on December 6. No papers in Natural Science will be set, but in the election to one of the Exhibitions preference will be given to any candidate who shall undertake to read for honours in Natural Science, and to proceed to a Degree in Medicine.

CAMBRIDGE.—The Grace for confirming the resolution of the Syndicate on titular degrees for women was rejected by 1707 votes to 661. The opposition of the majority of the residents has thus been unmistakably endorsed by the non-resident members of the Senate. It is probable that the question of admitting women to the membership of the University, whether by stages or directly, will not again be raised. The suggestion that powers should be obtained enabling the women's colleges to confer degrees on their own students will now have a better chance of calm consideration. The University might long continue to teach and examine the women students, while the titles which have been sought by them as necessary for their professional success might in this way be acquired without endangering the peace of Cambridge as a place of education for men.

Prof. Rücker, Sec.R.S., will give the Rede Lecture on "Terrestrial Magnetism," in the Senate House, on Wednesday, June 9, at noon.

The General Board of Studies propose to establish a University Lectureship in Experimental Psychology, including the physiology of the senses, at a stipend of 50*l*. a year. The appointment will probably be made next month.

Prof. Hughes, F.R.S., and Mr. P. Lake, of St. John's College, are appointed to represent the University at the International Geological Congress to be held at St. Petersburg in the summer.

FIELD-MARSHAL SIR JOHN LINTORN SIMMONS, G.C.B., will distribute the prizes to the students of the Charing Cross Hospital Medical School, on Wednesday, June 2, at 4 o'clock.

MRS. JOSIAH M. FISKE has given to Barnard College, of New York City, one hundred and forty thousand dollars for a new dormitory. Other gifts of considerable aggregate value have also been recently received by the college. Gifts are constantly pouring in on Columbia University; and the new buildings for these two institutions are rapidly rising on the new site on Morningside Heights.

THE following are among recent appointments:—Dr. E. Fischer to be full Professor of Botany in the University of Berne, and Director of the Botanical Gardens there; Dr. G. Jäger to be Assistant Professor of Theoretical Physics in the University of Vienna; Dr. F. Gräfe to be Assistant Professor of Mathematics in the Polytechnic Institute at Darmstadt; Dr. F. Deichmüller, Privat-docent in Astronomy and Observer in the Bonn Observatory, to be Assistant Professor.

THE Lords of the Committee of Council on Education are taking steps to ascertain the number of pupils now receiving secondary education in England in endowed, proprietary, and private schools. It is not proposed to include in the return any pupils who are only receiving instruction in occasional classes or evening schools; and technical institutes (except in so far as they have secondary day schools) and University colleges will fall outside the scope of the inquiry.

IN the House of Lords, on Friday, Lord Norton asked the Lord President whether he hoped to be able to introduce a Bill on secondary education this Session; or, if not, early next year. The Duke of Devonshire replied that he did not entertain any hope that Parliament would be asked to deal seriously with the subject in the course of the present Session. He hoped, however, that there would be laid before Parliament a Bill the main proposals of which were contained in the Bill of last year, so far as they related to secondary education, with some amendments and additions, in order that the general views of the Government might be once more placed before the country, and that the country might be in a position to consider them during the vacation.

SCIENTIFIC SERIALS.

THE most important paper in the numbers of the *Journal of Botany* for April-May is the completion of Mr. I. H. Burrill's very interesting notes on the fertilisation of spring-flowering plants on the Yorkshire coast. A series of careful observations are recorded on the species of the insect-visitors and the frequency of their visits.—Welwitsch's African collections are still affording to Messrs. W. and G. S. West a large number of new species of desmids.

IN the *Nuovo Giornale Botanico Italiano* for April are only two short papers on structural botany.—Sig. I. Baldrati describes the peculiar excrescences (*pellule*) found on the bulbs of certain species of *Allium*, which he decides to be of a foliar character.—Sig. E. Matteucci speaks of the structure of the corky spots in leaves, which are of the nature of lenticels.—The remaining papers are descriptive.

THE papers in the numbers of the *Bullettino de la Soc. Botanica Italiana* for February-April are also mostly descriptive.—Sig. G. Mattej discourses on the red spots found on the leaves and petals of a number of plants, and of the gum-resinous substance which they contain.—Sig. L. Macchiati returns to the vexed question of the peculiar structure of the seeds of *Vicia narbonensis*, which he declares to present marked differences from those of allied species.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 8.—"Kathode and Lenard Rays." By J. A. McClelland, M.A. Received March 15.

The experiments described in this paper have to do partly with kathode, and partly with Lenard rays.

An arrangement is described by which the charge of electricity carried by the kathode rays can be directly measured, and the same method is then applied to the Lenard rays, which are found to carry a similar negative charge.

In one set of experiments the Lenard rays are examined inside the tube, the kathode rays being allowed to fall upon a screen of thin aluminium, and the charge that is carried by the Lenard rays on the further side of the aluminium measured.

In a second set of experiments, a window of oiled silk is placed in the vacuum tube in the path of the kathode rays, and here, again, the charge carried by the Lenard rays outside the tube can be detected and measured.

It can also be shown that there is a negative discharge from the window by placing a plate of ebonite opposite the window, and dusting it over, after exposure, with minium and sulphur. The well-known negative figure is produced on the plate.

The Lenard rays appear to be simply a secondary propagation of kathode rays, produced by the rapid pulsations of negatively charged particles up to the aluminium screen. Measurements of the amount of electricity carried by these charged particles show that the electrostatic effects produced when they are stopped at the screen are sufficient to produce discharge on the further side of the screen, and a secondary stream of kathode rays. All the observed properties of Lenard rays admit of explanation on the theory that, like the kathode rays, they consist of a stream of charged particles.

In the paper an arrangement is described to measure the portion of the current actually carried by the kathode rays in a vacuum tube. With the tube used, even at a pressure at which there was little phosphorescence, a considerable fraction (more than 1/50) of the whole discharge was carried away from the kathode by the negative rays, while at lower pressures these rays carried a large portion of the discharge.

Chemical Society, April 29.—Prof. Dewar, President, in the chair.—The following papers were read:—On the explosion of chlorine peroxide with carbonic oxide, by H. B. Dixon and E. J. Russell. On exploding a mixture of carbonic oxide and chlorine peroxide, less of the carbonic oxide is burnt as the

mixture is the more carefully dried; this result does not favour the view that "nascent" oxygen attacks carbonic oxide more readily than ordinary oxygen.—On the decomposition of iron pyrites, by W. A. Caldecott. The "slime" obtained on crushing auriferous pyritic Witwatersrand conglomerate contains no ferrous sulphide as it leaves the battery, but this substance can be detected in the slime soon after deposition in the dams; ferrous sulphide is also formed when iron pyrites is crushed to an impalpable powder in a mortar. It would thus appear that ferrous sulphide, and not sulphate, is the first decomposition product of pyrites.—Monochlordiparaconic acid and some condensations, by H. C. Myers. Monochlordiparaconic acid, $C_9H_9ClO_2$, is obtained on treating dichlormethylparaconic acid with barium hydroxide.—Corydaline, Part v., by J. J. Dobbie and F. Marsden. On heating corydaline with dilute nitric acid, dehydrocorydaline nitrate $C_{22}H_{25}NO_4,HNO_3$ is formed, and if the action of the acid be pushed further, corydic acid, $C_{14}H_9N(OMe)_2(COOH)_2$, is obtained; on oxidising this with permanganate, at least four different acids are produced.

May 6.—Prof. Dewar, President, in the chair.—The following papers were read:—A Bunsen burner for acetylene, by A. E. Munby. A modified form of Bunsen burner for use with acetylene is described, which has a much greater heating effect than a Bunsen consuming an equal volume of coal-gas instead of acetylene.—The reactions between lead and the oxides of sulphur, by H. C. Jenkins and E. A. Smith. The authors find that Hannay's hypothetical compound, PbS_2O_2, the formation of which was premised in order to explain the reaction between sulphur dioxide and lead, and between air and galena at high temperatures, does not exist. The investigation of other of the reactions of lead salts at high temperatures prove the accuracy of the equations which Dr. Percy gave as the basis of the metallurgy of lead.—X-ray photographs of solid alloys, by C. T. Heycock and F. H. Neville. The authors have applied the fact that some metals, such as sodium and aluminium, are comparatively transparent to X-rays, whilst others, like gold, are opaque, to the investigation of alloys; a thin section is cut from the alloy to be examined, and an X-ray photograph obtained of it. Examined thus, pure sodium shows no crystalline structure, but alloys containing 3-10 per cent. of gold show transparent sodium crystals interspersed with opaque gold crystals. Many other gold-sodium and some aluminium alloys have been examined by this new method.

Entomological Society, May 5.—Mr. Roland Trimen, F.R.S., President, in the chair.—Mr. C. H. Peers was elected a Fellow of the Society.—Mr. J. J. Walker exhibited an earwig, *Apterygida arachidis*, Yersin, new to Britain, and recently found in large numbers in chemical works at Queenborough. It had been probably imported among bones.—Mr. Burr showed a complete series of the British species of Forficulidæ.—Mr. Enock showed eggs of *Stenopsocus cruciatus*, L., containing parasitic larvæ of *Alaptus fusculus*, Hal., the male of which would probably prove to be *Alaptus minimus*, Hal.—Mr. Merrifield exhibited the results of temperature experiments on the pupæ of *Pieris daplidice*, *Melitæa didyma*, and other species. He thought that changes produced by abnormal temperatures might be classed as follows: (1) enhancement or diminution of intensity of colour without alteration in the form of the markings; (2) substitution of scales of a different colour, scattered or in groups; (3) imperfection in the development of scales or their pigment.—Mr. Tutt showed a series of insects collected at Cannes in March, and remarkable for their early emergence.—Dr. Dixey read a paper on mimetic attraction, in which he dealt with the steps by which a wing-pattern, as in South American Pierinæ, could be modified in various directions so as to secure a mimetic result, and with the theories of mimicry put forward by Bates and Fritz Müller.—Mr. Blandford exhibited and discussed series of homœochromatic and mimetic Neotropical species of butterflies, chiefly of Heliconiidæ and Heliconioid Danaidæ. The discussion was continued by Prof. Poulton, who showed similar groups of several genera, remarkable as having been collected and sent to England as examples of a single species, and by the President, and it was ultimately adjourned to June 2.

Geological Society, May 12.—Dr. Henry Hicks, F.R.S., President, in the chair.—The following communications were read:—On the gravels and associated deposits at Newbury (Berks), by E. Percy Richards. After a general sketch of the geology of the Valley of the Kennet, the superficial deposits at and in the neighbourhood of Newbury were described in detail, from observations made by the author during the progress of the main drainage-works in 1894. The author classified the strata which he examined into five groups: (1) The Preglacial Southern Drift; (2) the Glacial Drift (Donnington); (3) the Upper River-gravel; (4) the Lower River-gravel; (5) the Neolithic peat-beds (shell-marl, peat, and loam).—The Mollusca of the Chalk Rock, Part ii., by Henry Woods. The first part of this paper, dealing with the Cephalopoda, Gasteropoda, and Scaphopoda, appeared in the last volume of the *Quarterly Journal* (vol. lii. p. 68). In the new communication the author gave an account of the characters, synonymy, and distribution of the Lamellibranchia: 29 species were recognised, 6 being new. In the concluding part the author compared the fauna of the *Reussianum*-zone (Chalk Rock) in England with that of other European areas, particularly North-West Germany and Saxony. In the latter country the number of species in some groups—particularly Gasteropoda and Lamellibranchia—was much greater than in England; this difference was probably due to the sea having been of less depth than in the English area. It was noticed that the species of Cephalopoda had a much wider geographical distribution than the other groups of the Mollusca. Finally, by a study of the present distribution of the genera—particularly of those which formed the predominating element in the fauna—taken in conjunction with the other characters of the zone, the author arrived at the conclusion that in England the *Reussianum*-zone was probably formed between the depths of 100 and 500 fathoms.

Mathematical Society, May 13.—Prof. Elliott, F.R.S., President, in the chair.—The following communications were made:—On cubic curves as connected with certain triangles in perspective, by S. Roberts, F.R.S.—Determination of certain primes, by F. W. Lawrence.—An analogue of anharmonic ratio, by J. Brill.—An essay on the geometrical calculus (continuation), by E. Lasker.—On the partition of numbers, by G. B. Mathews.—Notes on synthetic geometry, by W. Esson, F.R.S.

Zoological Society, May 18.—Prof. G. B. Howes in the chair.—Mr. Sclater exhibited a plan of the new Zoological Garden attached to the Pará Museum, Brazil, and called attention to the description of it recently published in the "Der Zoologische Garten" by Herr Meerwarth.—Mr. Sclater exhibited the skin of a penguin which he had received in exchange from the Musée d'Histoire Naturelle of Paris as a specimen of *Microdiptes serresianus* (Oust.); and read a note from Mr. Ogilvie-Grant, according to which this specimen was only an immature example of the Rock-hopper penguin (*Eudyptes chrysocome*).—Mr. R. E. Holding exhibited a skull of a Theban goat (*Capra hircus*, var. *thebaica*), and made remarks on the shortening of the skull in this and other domesticated animals.—Mr. G. A. Boulenger, F.R.S., read a paper entitled "A Revision of the Lizards of the Genus *Sceloporus*." From a study of the large mass of material in the British Museum, the author had come to the conclusion that the difficult genus *Sceloporus*, so far as was at present known, consisted of thirty-two species. Nearly all the specimens examined, with the exception of very young ones, had been measured, and their dimensions and the number of scales and femoral pores possessed by each of them were recorded in the paper. One new species (*Sceloporus asper*) was described.—Dr. G. Herbert Fowler read the second of a series of papers on the Plankton of the Faeroe Channel, which dealt with the distribution of *Conchœcia maxima* (a midwater or mesoplankton form), with the European species of *Tomopteris*, and with the distribution of *Tracheloteuthis riisei*.—Mr. Martin Jacoby contributed the second part of a paper on the Phytophagous Coleoptera of Africa and Madagascar. Nine new genera and eighty new species of the families *Eumolpinæ*, *Halticinæ*, and *Galerucinæ* were described.—Mr. W. G. Ridewood read a paper on the structure and development of the hyobranchial skeleton of *Pelodytes punctatus*.—Messrs. Oldfield Thomas and R. Lydekker, F.R.S., contributed a paper on the number of grinding-teeth possessed by the Manatee. From an examination of several specimens of this animal it had been ascertained that the number of its grinding-teeth was not a fixed one, but that it developed a continuous and indefinite number to replace those which had become worn away by the sand which was necessarily present in somewhat large quantities in its food of water-weeds.

Royal Meteorological Society, May 19.—Mr. E. Mawley, President, in the chair.—Mr. F. Gaster, of the Meteorological Office, read a paper by Mr. R. H. Scott, F.R.S., and himself,

on the mean monthly temperatures of the British Isles. The authors dealt with the means of the daily minimum, average, and maximum temperatures for the various months of the year in the twenty-five years 1871-95. They pointed out that there is a great difference between the amount of range of temperature at the coast stations and that recorded inland. The range between January and July amounts to about 16° at coast stations, but to more than 23° at the inland stations. The contrast between the temperature of the air at inland stations and at coast stations at different times of the year is due to the following causes: (1) The constant tendency of the sun to heat the surface of the earth; (2) the equally constant tendency of the earth to radiate its heat into space, both of these being modified greatly by the aqueous vapour and the clouds suspended in the atmosphere; (3) the fact that the solid portions of the earth absorb and reflect heat much more rapidly than the water; and (4) that while the ocean to the westward is of enormous size and great depth, the sea to the eastward is, comparatively speaking, limited in area and shallow, and separates the eastern shores of the British Islands from those of continental Europe by a small distance.—A paper, by Mr. C. V. Bellamy, on the rainfall of Dominica, West Indies, was also read. The author gave an interesting account of the climate of the island, and then discussed the monthly returns of rainfall from twenty-seven stations during the four years 1893-96. The rainy season extends from July to November, the other months representing the dry season. The month of November, 1896, was the wettest on record.

PARIS.

Academy of Sciences, May 17.—M. A. Chatin in the chair.—On the photographic atlas of the moon, published by the Observatory of Paris (second part), by MM. Lœwy and Puiseux.—Signification of appendices and their symmetry in the measurement of gradation in vegetable species, by M. Ad. Chatin. Plants are classified into two large groups, according as they have appendices or not. The symmetrical relations between the appendices serve to further subdivide the larger series.—Fourth note on the applications of radioscopy to the diagnosis of diseases of the thorax, by M. Ch. Bouchard. The preceding notes deal with the applications of radioscopy to the diagnosis of pleurisy, pulmonary tuberculosis, and hypertrophy of the heart. In the present note four cases are described: one of cancer of the œsophagus, and three of diseases of the aorta subsequent to acute rheumatism, in all of which the examination by the Röntgen rays proved to be of great service.—Demonstration by the Röntgen rays of the osseous regeneration in man after surgical operations, by M. Ollier. Studies of this nature have hitherto been very difficult, owing to the fact that accidental deaths at suitable stages in the osseous development are necessarily rare. The form and dimensions of the osseous masses in the new formation can now be readily demonstrated by means of the X-rays. The exact knowledge afforded in this way of the position of diseased bone (as in osteo-myelitis), renders unnecessary the immediate amputation of the limb, since the whole of the diseased portions can be removed with precision.—Disturbances in lakes and hurricanes, by M. F. A. Forel. It is shown that sudden barometric changes of the order of magnitude actually registered on one or two occasions are sufficient to account for the extraordinary changes of level occasionally observed on the Lakes Leman and Geneva. The effects are magnified by interference, and by the narrowing down of the lake.—M. Klein was elected a Correspondant of the Academy in the Section of Geometry, in the place of the late Prof. Sylvester.—Converse theory of binomial theorem, by M. Sitanath Chakrabarthy.—On the medicinal properties of *Œnothera biennis*, by M. Lewis Germain.—On the curves of which the tangents belong to a complex, by M. A. Demoulin.—On some applications of the theory of cyclic systems, by M. C. Guichard.—On a graphical method of integration for differential equations, by M. Michel Petrovitch. A mechanical apparatus is described capable of integrating all equations of the form $\Phi(y)\, dy/dt + \lambda \sqrt{y} - af'(t) = 0$, and of certain other equations derived from this by suitable substitutions.—On the kathode rays and some phenomena in vacuum tubes, by M. C. Maltézos. Experiments are described leading to the conclusion that anode light consists of matter carrying positive electricity.—On the transparency of ebonite, by M. Perrigot. Ebonite in thin films (0·5 mm.) is obviously transparent to red light, and light after passing through ebonite produces distinct effects upon orthochromatic plates rendered sensitive to the red and yellow rays. Ebonite plates 2 mm. in thickness, although opaque to the eye, still affect the photographic plate. These results confirm those of M. Becquerel as to the true cause of the effects observed by M. Le Bon.—New determinations of gravity, by M. J. Collet. The results of a series of pendulum observations along the forty-fifth parallel of latitude. The final results are compared with those calculated by Defforges' formula, the experimental results being always slightly lower than the theoretical.—On lithium borate, by M. H. Le Chatelier. The monoborate $LiBO_2$ is readily obtained in the dry way; it dissolves, readily forming the hydrate $LiBO_2 8H_2O$. The solubility curve shows some peculiarities, there being a temperature of maximum solubility. The heats of hydration, solution, and combination were determined. In the wet way, a diborate analogous to borax is formed, but the salt is so soluble that it could not be isolated.—On the alloys of the silver-copper group, by M. F. Osmond. In spite of the fact that the alloy containing the metals in the proportions indicated by Ag_3Cu_2 is the only one that does not liquate on solidifying, the alloy is not a homogeneous compound, but a mixture. The results of Heycock and Neville on the melting points of the copper zinc alloys indicate this, and the micrographical study affords results leading to the same view.—Researches on the coloration of glass by the direct penetration of metals or metallic salts, by M. Léon Lémal. Glass of a suitable composition can be coloured by a process similar to cementation at temperatures between 500° and 550° C. With silver salts a reddish orange stain is produced.—Remarks by M. Armand Gautier on the preceding note.—The action of water upon phosphoryl trichloride, by M. A. Besson. By the action of small quantities of water upon $POCl_3$ at 100°, several chlorides appear to be produced, from which pyrophosphoryl chloride, $P_2O_3Cl_4$, can be isolated and analysed in a fairly pure state. The residue is stated to consist of metaphosphoryl chloride, but no analyses are given, nor any indications that the residue was a homogeneous substance. The action of water is thus shown to be analogous to that of hydrogen sulphide.—On some new symmetrical aromatic ureas, by MM. P. Cazeneuve and Moreau. The authors conclude from their experiments that the best method of preparation of symmetrical substituted ureas is by acting with primary bases upon the carbonic ethers of the phenols, especially upon the carbonate of guiacol.—On the amido-amidines, by M. Charles Lauth.—*Rôle* of tannins in plants, and especially in fruits, by M. C. Gerber. One of the chief functions of tannin appears to be to prevent pectic transformations, and hence to prevent the fermentation of their sugars. In fruits containing tannins, these disappear completely by oxidation without giving rise to any carbohydrates.—On the *Pseudocommis vitis* (Debray), and on new proofs of the existence of these Myxomycetes, by M. E. Roze.—The clear rings ("lunure") in sections of oak wood, by M. Emile Mer.—Physiological disturbances due to the X-rays, by M. Destot. The differences between the effects of exposure to the sun and X-rays are clearly marked, the latter not being felt at the moment of application, and only becoming evident after a considerable time.—Researches on the causes of disturbances due to growth with the aid of the X-rays, by MM. Maurice Springer and D. Serbanesco.—Rule for solving two numerical equations of any degree with two unknowns, by M. Teguor.

ST. LOUIS.

Academy of Science, May 3.—Mr. H. von Schrenk spoke of the respiration of plants, with special reference to the modification of those growing with their roots submerged in water. The lecture was illustrated by a demonstration of the liberation of carbon dioxide in respiration from the roots of an ordinary flowering plant and freshly gathered fungi, and the more usual ærenchyma structures were made clear by the use of lantern slides.—Prof. F. E. Nipher described a simple means of measuring the resistance of a tube to the flow of air, when compared with an accepted standard, by the use of a tubular device, similar in principle to the Wheatstone bridge used in electrical instruments; the apparatus, in the present instance, consisting of parallel tubes filled with air, connected by a tubular bridge, in the middle of which a drop of water was placed, so as to change position with the variations in the flow of air on the one hand or on the other.

AMSTERDAM.

Royal Academy of Sciences, April 21.—Prof. van de Sande Bakhuyzen in the chair.—Prof. Haga communicated a method of determining the wave-length of X-rays. This method,

the result of experiments made by Mr. P. G. Tiddens, of Gröningen, is founded upon the fact that a perfectly identical deflection image is produced by rays of very different wave-length, by varying the distance between the source, the diffracting slit, and the screen in a definite manner. Starting from a diffraction image of light rays, provisional experiments were made to determine whether the wave-length of X-rays was equal to, or one-quarter or one-fifteenth of, that of light rays. In the last-mentioned case, the image resembled that obtained from light rays more than the others did; it was not, however, quite identical with it —Prof. Haga read a paper, by Dr. C. H. Wind, on the influence of the dimensions of the light beams on Fresnel's diffraction phenomena, and on the diffraction of X-rays. From experiments, made by Mr. Tiddens, it appeared that the X-shadow figures obtained by Fomm and others, are not ordinary Fresnel diffraction images. The author showed that the shadow figures obtained are to be conceived as secondary diffraction images (arising from ordinary ones on the slit serving as a source of light being widened), and he developed the main points of the theory of these secondary diffraction images, and pointed out the way it opens to determining the wave-length. The existence of secondary diffraction phenomena, analogous to those observed when employing X-rays, can easily be ascertained when ordinary light is used. This, in the author's opinion, as good as proves the undulatory character of X-rays.—Mr. Hamburger communicated a new quantitative method of determining the anti-bacterial action of blood and tissue fluid. This method avoids the usual counting of microbes with the help of plate cultures, because this occasions errors of 40 to 50 per cent. Instead of counting the microbes, their total volume is determined by centrifugal action. This method occasioned errors of only 6·5 per cent.—Prof. van der Waals presented, for publication in the *Proceedings*, a paper on the equilibrium of a compound solid in the presence of a gas and a liquid. The author proves that by adding to the ψ surface for a mixture (*Arch. Néerl.*, t. xxiv.) a ψ line for the solid, the laws of these phenomena can be deduced in a simple way by geometrical construction.

DIARY OF SOCIETIES.

THURSDAY, MAY 27.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.

FRIDAY, MAY 28.

ROYAL INSTITUTION, at 9.—The Isolation of Fluorine: Prof. H. Moissan.
PHYSICAL SOCIETY, at 5.—The Perception of Difference of Phase by the Two Ears: Dr. A. A. Gray.—The Isothermals of Isopentane: Mr. Rose-Innes.

SATURDAY, MAY 29.

LONDON GEOLOGICAL FIELD CLASS.—Excursion to Sheerness. Drive to East Church, Hensbrook. London Clay. Leave Holborn Viaduct, 1.25.

MONDAY, MAY 31.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Nupe and Ilorin (Nigeria): Lieut. Seymour Vandeleur.

TUESDAY, JUNE 1.

ROYAL INSTITUTION, at 3.—The Heart and its Work: Dr. E. H. Starling.
ZOOLOGICAL SOCIETY, at 8.30.—On the Structure of the Skull in the Paraguayan Lepidosiren: Prof. T. W. Bridge.—On the Classification of the *Thyrididæ*, a Family of the Lepidoptera Phalænæ: Sir George F. Hampson, Bart.—On a Collection of Lepidoptera obtained at Shoa in 1894 by Mr. F. Gillett: Dr. A. G. Butler.

WEDNESDAY, JUNE 2.

ENTOMOLOGICAL SOCIETY, at 8.
VICTORIA INSTITUTE, at 4.30.—Annual Meeting.—Address by Lord Kelvin.

THURSDAY, JUNE 3.

ROYAL SOCIETY, at 4.—Election of Fellows.——At 4.30.—*Probable* Papers: The Sensitiveness of the Retina to Light and Colour: Captain Abney, F.R.S.—On the Mechanism by which the First Sound of the Heart is produced: Sir R. Quain, F.R.S.—Mathematical Contributions to the Theory of Evolution. On the Relative Variation and Correlation in Civilised and Uncivilised Races: Miss Alice Lee and Prof. K. Pearson, F.R.S.—An Investigation on the Variability of the Human Skeleton, with especial reference to the Naquada Race, discovered by Prof. Flinders Petrie in his Explorations in Egypt: E. Warren —On the Brains of Two Sub-Fossil Malagasy Lemuroids: C. I. Forsyth Major.—(1) On the Dielectric Constants of certain Frozen Electrolytes, at and above the Temperature of Liquid Air; (2) On the Dielectric Constants of Pure Ice, Glycerine, Nitrobenzol, and Ethylene Dibromide, at and above the Temperature of Liquid Air: Prof. Fleming, F.R.S., and Prof. Dewar, F.R.S.—Preliminary Communication on the Nature of the Contagium of Rinderpest: A. Edington.
LINNEAN SOCIETY, at 8.—Observations on Termites: Dr. G. D. Haviland. —On the Genus Ramulina: Prof. T. Rupert Jones, F.R.S., and F. Chapman.
CHEMICAL SOCIETY, at 8.—On the Thermo-chemistry of Carbohydrate Hydrolysis; On the Thermal Phenomena attending the Change in Rotatory Power of Freshly-prepared Solution of certain Carbohydrates, with some Remarks on the Cause of Multirotation: Horace J. Brown, F.R.S., and Spencer Pickering, F.R.S.—Optical Inversion of Camphor; Derivatives of Camphoric Acid. Part II. Optically Inactive Derivatives; Racemism and Pseudo-racemism: Dr. F. S. ROCK-WEATHERING.

A Treatise on Rocks, Rock-weathering and Soils. By George P. Merrill, Curator of Geology in the U.S. National Museum. Pp. xx + 411. (New York: The Macmillan Co. London: Macmillan and Co., Ltd., 1897.)

"THE ruins of an older world are visible in the present structure of our planet; and the strata which now compose our continents have been once beneath the sea, and were formed out of the waste of pre-existing continents. The same forces are still destroying, by chemical decomposition or mechanical violence, even the hardest rocks, and transporting the materials to the sea, where they are spread out, and form strata analogous to those of more ancient date." These memorable words of Hutton, written more than a century ago, have been appropriately selected by the author as the motto for his work, the main object of which is to describe the various processes of rock degeneration and soil formation.

The book is divided into five parts, dealing with the constituents of rocks, the different kinds of rocks, the weathering of rocks, the transportation and re-deposition of rock débris, and the mantle of unconsolidated material which covers the greater portion of the land surface, and for which the author proposes the term "regolith."

The first two parts are not remarkable, either on account of the matter contained or the mode of treatment. The author somewhat disarms the critic, so far as these parts are concerned, by stating in the preface that "the work must be considered in no sense a petrology, as this word is commonly used"; nevertheless, we feel justified in pointing out that much which is inserted might have been omitted without detriment to the work so far as its main object is concerned, and much that is omitted might appropriately have found a place. Thus the first part contains scraps of information about the characters of rock-forming minerals, which are insufficient for the beginner, and are not required by the advanced student. More serious are the omissions. In a work dealing with the disintegration and decomposition of rocks, we naturally look for a somewhat detailed account of the pathological characters of the primary constituents of the crystalline rocks, and of the physical and chemical conditions under which the various secondary products arise. Very little information is, however, given on these points; and this is all the more remarkable, because the works of Roth, and the numerous and important papers by Lemberg, referred to by the author, would have readily supplied him with a large amount of the necessary material.

The classification of rocks adopted by the author is simple, natural, and well suited to his purpose. The igneous rocks are divided into nine groups, depending mainly on chemical composition, and are defined by taking the plutonic and volcanic representatives of the several groups. Thus we have the granite-liparite group, the foyaite-phonolite group, the gabbro-basalt group, and so on. The author does not favour the modern tendency to introduce new names for comparatively unimportant local varieties, and protests against "such monstrosities of nomenclature as ovachichite, monchiquite, yogoite, and absarokite."

The descriptions of the rocks are generally accurate, but we have noted one or two imperfections. Thus the statement that "chert is an impure flint, containing not unfrequently nummulitic remains," appears somewhat strange when one remembers that cherts are of all ages, and that they are largely due to accumulations of sponge spicules and radiolaria.

The unpleasant task of fault-finding ends with the consideration of Part II. In the remaining parts which make up the main body of the work we have an admirable presentation of the various phenomena connected with the disintegration and decomposition of rocks, the transportation of rock-débris, and the formation of soil. Part III. deals with weathering. The action of the atmosphere, the chemical action of water, the mechanical action of water and ice, and the action of plants and animals, including the nitrifying organism, are severally discussed in detail. Then follows a special chapter, based largely on the author's original work, and containing some hitherto unpublished material, in which special cases of decomposition are described. The cases have been carefully selected, chemical analyses of the fresh and decomposed rocks are given, and these are supplemented by mechanical analyses of the latter. In a few instances, chemical analyses of the different parts into which the decomposed rock can be separated by mechanical means are also given. This exhaustive study necessarily brings out a number of points of great interest, only one or two of which can be referred to.

To illustrate the method of treatment, we quote below a table representing the analyses of fresh and decomposed gneiss from Albemarle County, Virginia—that is, from a region outside the area of glaciation, and one in which the rocks have, therefore, been subjected for a long period to atmospheric influences.

—	I. Bulk analysis of fresh gneiss.	II. Bulk analysis of decomposed neiss.	III. Loss.	IV. Percentage of each constituent saved.	V. Percentage of each constituent lost.
Silica	60·69	45·31	31·90	47·55	52·45
Alumina	16·89	26·55	0·00	100·00	0·00
Ferric oxide	9·06	12·18	1·30	85·65	14·35
Lime	4·44	trace	4·44	0·00	100·00
Magnesia	1·06	0·40	0·80	25·30	74·70
Potash	4·25	1·10	3·55	16·48	83·52
Soda	2·82	·22	2·68	4·97	95·03
Phosphoric acid (P_2O_5)	0·25	·47	0·00 [1]	100·00	0·00 [1]
Ignition	0·62	13·75	0·00 [1]	100·00	0·00 [1]
	100·08	99·98	44·67	—	—

A comparison of the bulk analyses of the fresh rock, and the incoherent material resulting from its decomposition, necessarily gives, in many cases, a very imperfect

[1] Gain.

F

idea of the change which has taken place. Some constituents are readily removed; others, especially the alumina, are comparatively insoluble under ordinary conditions, and therefore remain behind. Thus, Columns III., IV. and V. show the loss or gain of the various constituents estimated on the basis of constant alumina. We may remark, in passing, that alumina may be removed under certain conditions; as, for example, when sulphuric acid is formed by the oxidation of pyrites. This shows the necessity of caution in taking alumina as the basis of comparison, but it does not affect the present case. From Column III. we learn that 31 per cent. of silica, 1·3 of ferric oxide, the whole of the lime, and the greater part of the magnesia and alkalies have been removed. The total loss amounts to 44 per cent. In this case, the breaking down of the rock has been accompanied by decomposition as well as disintegration; in other cases decomposition is not so prominent, and the total loss is consequently much less.

Many rocks are treated in the same way, but one other illustration must suffice, and for the complete data in this case we must refer the reader to the book itself. In certain parts of America, and indeed in all countries where limestones are extensively developed, and where the residual products of decomposition are allowed to accumulate for a considerable length of time, a superficial deposit of red or brown clay is formed. In these cases the author considers that silica may be assumed to be constant, and taken as the basis for calculating the amount of material removed. He thus arrives at the conclusion that in the particular case described by him 97 per cent. of the original limestone has disappeared. In some localities residual clays of this kind attain a thickness of from 20 to 120 feet.

Having considered in detail a number of special cases in the manner above described, the author proceeds to deal with the influence of joints of texture, of mineralogical composition, of climate, and many other factors. All these points are discussed in the light of recent knowledge, and the chapters devoted to them are full of interesting and important information. Illustrative cases are mostly drawn from American sources, and this gives to the book a refreshing novelty, at any rate to English readers, even when well-known principles are treated. Especially interesting are those portions dealing with climate. It is pointed out that in cold and dry climates, subject to extremes of temperature, disintegration is the dominant factor; whereas in moist, warm climates decomposition is very pronounced. Thus the careful study of the petrographical character of sediments may be expected to throw important light on the climatic conditions of those regions which furnished the material. This point is, of course, not new; but its importance has not been fully recognised, and it is therefore satisfactory to see that the author gives it a prominent place.

The concluding part of the book deals with the superficial deposits for which the term regolith is proposed. Under this term is included not only the soil, subsoil and residual products of decomposition, but also the alluvial, æolian, and glacial deposits. We are by no means convinced that the author was well advised in departing from his general and most praiseworthy determination to avoid as much as possible the introduction of new terms; but the point is, after all, of comparatively slight importance. If the term supplies a want, it will come into general use; if not, it will die out.

The petrographical characters and conditions of formation of the various deposits classed as the regolith are described, and we are glad to see that special attention is paid to the æolian formations, as these often receive scant courtesy at the hands of geologists. Loess, however, is discussed under alluvial deposits, although it is ascribed in part to the action of the wind. Surely there can be no doubt that typical loess is of æolian origin; and if, in America or elsewhere, alluvial deposits have been included under this term, this should be recognised as a mistake, and speedily rectified.

The work is admirably illustrated by twenty-five plates and numerous figures in the text, all of which have been produced in the manner so highly appreciated by those who are acquainted with American geological literature.

MECHANISM AND BIOLOGY.

Zeit- und Streitfragen der Biologie. Heft 2. *Mechanik und Biologie.* Von Prof. Dr. Oscar Hertwig. Pp. iv + 211. (Jena: Gustav Fischer, 1897.)

FROM the title of this work one might have expected a critical examination of the validity of the general principles of modern biology, more particularly of modern physiology; and such a criticism, from the pen of Dr. Oscar Hertwig, would have been welcome and instructive. It is with a feeling of disappointment that one finds that his criticism is almost entirely confined to a comparatively limited aspect of the question, and is, in fact, a polemical treatise directed especially against the pretensions and conclusions of Wilhelm Roux and his school. It is, no doubt, a simpler task to refute the theories of Roux; but if Dr. Oscar Hertwig is victorious in this particular argument, it must not be supposed that he has weakened, or that he has even attempted to weaken, the conviction held by the majority of biologists, that the explanation of vital processes is to be sought for on "mechanical" principles. There is, however, a considerable amount of obscurity attached to this word "mechanical" as applied to biological phenomena, and many pages of this book are devoted to pointing out the errors into which we may be led if we use the word in a loose and general sense, or if we confuse its philosophical with its physical meaning. In its widest sense a mechanism is a system of objects, which in place and time stand in a necessary relation to one another. Hence, when we describe the attitude of contemporary science as mechanical, we do but assert that science is convinced that the operations of nature are subject to the control of universal law. Of this the biological are as much convinced as the abiological sciences; yet this conviction does not necessarily lead to the conclusion that the methods of the abiological are in all respects applicable to the biological sciences. To discuss this question is to discuss the philosophical basis not only of biology, but of all the sciences. As a contribution to the discussion, Dr. Hertwig gives us copious quotations from Spinoza, Kant, Lotze and other philosophers, skilfully selecting such passages from these thinkers as best serve his immediate purpose of refuting Roux. His readers

would have profited had he taken a more detached view of his subject, and had attempted to define the grounds of our belief in the prevalence of universal law in biological phenomena without special regard to Roux or any other author.

In the second part of this book, Dr. Hertwig deals with the methods of developmental mechanics as put forth by Roux and his school. Roux is one of those who specially represents a modern tendency to magnify the importance of experiment in biological investigation, and to minimise the value of what is called "mere observation." It has been pointed out, over and over again, that there is no sharp distinction between experiment and observation, that some of the most complete, the most "mechanical" of the sciences—as, for example, astronomy—are, from the nature of things, sciences of observation, and that what we call experiment is but a means to an end, the end in every case being observation of the change of state following the disturbance which was the first step introduced by the experiment. Here, says Dr. Hertwig, there is a great difference between the inorganic and the organic world. Inorganic substances are relatively stable; the simple contemplation of them would lead to no result. It is only by disturbing their condition of equilibrium, by causing changes of state in them, that we can observe a succession of phenomena which will enable us to assert relations of cause and effect. With living things the case is different; they are in a constant state of flux, and observation presents us with an unbroken succession of changes whose laws may be traced by the aid of reflection. What is true of biology in general is especially true of the study of the development of organisms, since it is during their development that organisms exhibit the most numerous, the most constant, and the most unbroken succession of changes. In depreciating the results of observation, and in drawing a brilliant picture of the results which are to follow from the use of experiment in biology, Roux, and those who, like Yves Delage, have followed him, have fallen into the error of supposing that observation is necessarily an act of contemplation without reflection, and that reflection added to observation raises the last-named to a level which has neither been attained nor sought after by the majority of workers. Such an error is easily refuted by Dr. Hertwig, who shows that in the domain of embryology the method of observation has been strikingly fruitful of results; that embryologists have been distinguished for the readiness, sometimes by the over-eagerness, with which they have drawn conclusions as to cause and effect from the results of their observations; and, finally, that the much-praised method of experiment, when applied to embryological research, has been comparatively barren of result. We have, indeed, learnt some new and striking facts from the experiments of Driesch, Wilson, Zoja, and of Hertwig and Roux themselves; but the main result of these experiments has been to overthrow the speculations of the school which plumes itself on its insight into the mechanical processes of development.

To most persons the most interesting part of Dr. O. Hertwig's book will be the appendix, which contains critical observations on the mechanical laws of development promulgated by Roux. This author, it will be remembered, as a result of experiments and observations, made by him on the developing ova of the frog, formulated a series of developmental laws, of which the chief were: that the plane of the first segmentation coincides with the sagittal plane of the future embryo; that the four first blastomeres correspond to four definite regions, right and left anterior and right and left posterior of the future embryo; and so forth. From these so-called laws theoretical conclusions of wide applications have been drawn. It has been asserted that the organs and tissues of the adult are represented by equivalent ultra-microscopical particles in the ovum, and that these particles are distributed in the ovum in a manner corresponding to their prospective situation in the adult. The particular manner in which these hypothetical particles give rise, in the course of development, to the tissues and organs of the adult, is set forth in Roux's theories of self-differentiation and mosaic-work. Dr. Oscar Hertwig deals in detail with the developmental laws of Roux and their consequences, and shows that, in the first place, the laws have no validity, and that, therefore, in the second place, the conclusions drawn from them are without foundation. Roux destroyed one of the first two or four blastomeres of the frog's ovum, and stated that the embryo resulting from the development of the remaining blastomere or blastomeres was a half embryo or quarter embryo, deficient in those parts which were contained in the blastomeres which had been destroyed. Hertwig, repeating the same experiments, showed that destruction of any of the earliest blastomeres does not, in fact, lead to the results which were described by Roux, and that the early blastomeres might be, so to speak, shuffled up by means of pressure, and yet a perfectly normal embryo be formed. Hertwig's experiments are confirmed by those of Driesch, Wilson and Zoja, who have shown that if the first four blastomeres of echinoderms, of amphioxus, or of hydromedusæ are separated from one another, each gives rise to an embryo, normal in all respects, except that it is a quarter of the usual size. Such experiments point conclusively to the fact that the material of the egg is not qualitatively, but quantitatively divided in the first stages of segmentation, and that Roux's theories of mosaic-work and self-differentiation are, therefore, without foundation. In the appendix to this book the experiments and conclusions of Roux, and the conflicting observations of Hertwig, Driesch and others, are given in a concise and easily intelligible form; and the reader will hardly fail to be persuaded that the balance of evidence is in favour of Hertwig's opinion. At the same time, it must not be forgotten that there is a considerable mass of evidence in favour of Roux's main proposition, that in *normal* development the first segmentation planes do mark out particular regions of the future embryo. Dr. Hertwig has handled Roux somewhat severely for his definitions of normal and abnormal development; but the truth seems to be this. That the ovum of any animal, if left to itself, will go through a course of development which may be called normal, of which one of the features is that the symmetry of the adult is expressed by the earliest cleavage planes. But this course of development, though normal, is not *necessary*. If the blastomeres be displaced, or even if they be separated, development will complete itself, and the end result is the same, though the first steps have been different. The conclusion is that

developing organisms, like adults, are possessed of considerable powers of adaptability. Exposed, for the most part, to very similar conditions, they develop in a very similar way, which we come to recognise as the normal way. But, if the conditions are varied within certain limits, the developing organism adapts itself to those changes, and completes the cycle of its existence. All the evidence, whether from the side of Roux, or from that of Hertwig, Driesch and others of the same opinions, shows that there is a very definite limit to the disturbances to which the developing ovum is capable of adapting itself. Such discussions as are contained in this book only serve to bring forward more prominently the view that the organism is the result of the interaction between its own specific nature and the environmen It would seem that the next essential step in biological inquiry is to determine in special instances what is the nature of the reaction of living substance to external conditions. Much has been attempted in this direction, but the results have hitherto been indefinite, and even contradictory.

THE EXAMINATION OF THE BLOOD IN DISEASE.

A Guide to the Clinical Examination of the Blood for Diagnostic Purposes. By Richard C. Cabot, M.D. With coloured plates and engravings. Pp. xix + 405. (London, New York, and Bombay: Longmans, Green, and Co., 1897.)

SINCE Hughes Bennett's observations on leucocythemia were recorded, great advances have been made in the methods of examining blood, and a certain limited number of physicians, appreciating the importance of the changes that take place in the blood as indicative of changes in the more fixed tissues, have laid considerable stress on the necessity of determining the exact constitution of the blood in certain forms of disease. With all this, however, the use of the various apparatus devised for such estimations have never come into general use. For this there appear to have been two principal reasons: (1) that the medical man has not considered that the information to be derived from such examination is at all commensurate with the time and skill required to obtain such information; (2) the second reason, which, however, is intimately bound up with the first, is that hitherto we, in this country at any rate, have been beholden for any systematic account of the pathology and clinical pathology of the blood to Hayem in France, and to Grawitz, Schmaltz and Rieder in Germany, as up to the present there has been no systematic treatise in the English language on the clinical examination of the blood. Indeed, in recent years, although much valuable work on the blood of animals artificially treated has been published by a number of our younger physiologists and pathologists, and although Gower's work has formed the basis of much of the clinical examination that has been done, it is to the impetus that Metchnikoff and Ehrlich have given to the study of the blood as a histological tissue that these advances have been made. A similar impulse seems to have been given in America, with the result that there has come from the Johns Hopkins Laboratories a work which, whilst based on the researches carried out in France and Germany, has nevertheless a certain individuality and value quite apart from that reflected in it from foreign workers. Dr. Cabot, approaching the subject from the point of view of a man who has made himself thoroughly familiar with the various methods of examining blood, having already examined the blood from nearly a thousand cases, and has at his command the observations on about three thousand more cases examined in the Massachusetts Hospital, gives an account of the structure of the blood, in which, however, it is evident that Ehrlich's observations have been made the basis of the descriptions, as outside Ehrlich's classification the accounts of the structure and appearance of the corpuscles are somewhat meagre, especially from the purely clinical point of view. In the accounts of the systematic work this is, perhaps, not altogether a disadvantage; still we think that those who come to compare this work with the results that they may obtain, either in clinical or in experimental work, will find that full use has not been made of more recent investigations, especially those that have been carried on in this country.

It is impossible, in a short review, to give more than a very meagre outline of this work; but, as it is really the first of its kind that has appeared in the English language, it may be well to indicate the enormous amount of matter that has been collected and arranged in handy form for reference. In the first instance, the methods of clinical examination of the blood are set forth, and from the completeness and accuracy of the descriptions given, and from the fact that the author is so frequently able to indicate the difficulties met with, and the methods of getting over them, it is evident that he has a thorough practical acquaintance with his work. We are glad to see that he insists very strongly upon the examination of the fresh blood—a method of examination which is far too little used in these investigations. The instruments recommended are all of German origin, and the difficulty that has hitherto been found by those working with these instruments are acknowledged. What strikes one very forcibly in this connection is the value of the "Tintometer" system as compared with any of those here mentioned. In describing the myelocytes—the non-motile marrow cells with their large, simple nuclei—Dr. Cabot appears to assign to mere mechanical conditions the regularity of the nucleus, and he says that "the absence of amœboid motion, and of journeys through tissues, leaves the nucleus evenly and moderately stainable throughout, while the amœboid blood leucocyte, through the wear and tear of its migrations, gets its chromatin irregularly distributed, condensed here, pulled out thin there, and hence stains unevenly or is mottled." This point is referred to on several occasions throughout the book. Surely the want of amœboid motion is indicative of the inactivity of the cell, the regularity of the nucleus pointing to the fact that it is in the so-called resting-stage, especially as it is indicated that marked degenerative changes may be observed in these myelocytes. We should feel strongly inclined to reverse Dr. Cabot's cause and effect. After an account of the methods of clinical examination and the physiology of the blood, several chapters are devoted to the general pathology of the blood, after which the bulk of the book is devoted to the special pathology of the blood, primary anæmias, leuk-

æmia and Hodgkin's disease being also very fully treated. Then the blood in acute and chronic infectious diseases, in diseases of special organs, in diseases of the nervous system, constitutional diseases and hæmorrhagic diseases, in malignant diseases in various positions, and, lastly, the blood in which parasites are present. We may take, as an example of the plan of the work, a short description given of the diagnostic value of blood examination in typhoid fever, in which Dr. Cabot notes post-febrile anæmia, sometimes very intense; no leucocytosis; later leucopenia; increased percentage of young leucocytes at the expense of adult forms, especially marked in this late period; most complications cause leucocytosis. Typhoid can be differentiated from local inflammatory processes by the fact that in uncomplicated conditions leucocytosis is never associated with it, whilst all local inflammatory conditions are accompanied by leucocytosis. Typhoid and malaria can, of course, be distinguished by the presence of the malarial organism in one, and its absence in the other. Even in acute tuberculosis, where leucocytosis is not present, the proportion of young leucocytes is, as a rule, larger in typhoid than in tuberculosis. A similar application of this method to other diseases promises excellent results, and we congratulate Dr. Cabot on having placed such a systematic and practical work in the hands of the medical and scientific worker, as we believe that a book of this kind will do more to encourage the study of the pathological conditions of the blood than anything that has appeared in recent years.

OUR BOOK SHELF.

The Forcing-Book: a Manual of the Cultivation of Vegetables in Glass-houses. By L. H. Bailey. Pp. xiii + 266. (New York: The Macmillan Company. London: Macmillan and Co., Ltd., 1897.)

THIS is a small manual devoted to an explanation of the principles, and to a statement of the practices involved, in "forcing for market." In no department of horticulture do experience and judgment tell more than in forcing operations; but if "practice" be essential, it is certain that to get the best results, it must be directed by trained intelligence. In this country market-gardening under glass has greatly extended of late years, and many agriculturists, finding it no longer remunerative to grow wheat, have turned their attention to the growth of flowers or to market-gardening generally. As a rule these men have been successful because they have known how to adapt themselves to new conditions, and have not been mere slaves to routine. As competition increases it may be expected that market-gardening will become less remunerative, and hence the necessity for increased knowledge and quickened intelligence in order to meet the new circumstances. In the United States, in Germany, in France, in Belgium, in Denmark, this truth has been recognised, and horticultural schools and experiment stations have been established for years. In this country, as is usually the case in such matters, we have lagged behind, and have many arrears to clear off before we can deem ourselves on a level with the countries we have mentioned. And all this time we are importing, to an enormous amount, commodities a large proportion of which might be grown at home.

The experimental station in connection with the Cornell University has taken a very prominent position in teaching the principles of cultivation, and in furnishing the opportunity of putting them into practice. Its bulletins have consequently been read with interest. The present volume is, to a large extent, based on these bulletins, and will be valued accordingly. Within its prescribed limitations the reader will find an epitome of the most advanced views on the culture of plants. Much of the book is taken up with technical details, which need only be referred to here; but we may refer the reader especially to the paragraph on the use of the electric light for forcing-houses, at p. 80. It is very short, but contains a great deal of information which will be serviceable to those who are contemplating further experiment. The results obtained are substantially the same as observed on different plants by the late Sir William Siemens; but, if we remember rightly, the time required to mature the crops and ripen the fruit at Tonbridge Wells was much less than has been ascertained to be necessary in the United States. Probably the discrepancy is easily to be explained by differences of circumstances. "It will be found profitable," says Prof. Bailey, "to use the electric light for plant-growing, if at all, only in the three or four months of midwinter." A general summary of the contents and a good index render the volume easy to consult.

The Birds of Our Country. By H. E. Stewart, B.A. Pp. viii + 397. (London: Digby, Long, and Co., 1897.)

THE Natural History Societies of our public schools should add this book to their libraries. It contains brief illustrated descriptions of all the birds likely to be seen in the British Isles, and will afford young observers a means of obtaining interesting information on bird-life. We hope the book will not add to the number of indiscriminate collectors. The author refers to "many an enjoyable day spent rambling through the [New] Forest in search of something which might be deemed worthy of a place in our collections, and possibly of a paragraph in a natural history paper to be read at one of our social evenings afterwards." The "takes" of such rambles are also mentioned. It would have been well if a word or two of advice had been added on the folly of collecting specimens without studying them. The young collectors into whose hands the book will probably fall, should be told distinctly that their hobby must be exercised with discretion.

The Pamirs and the Source of the Oxus. By the Right Hon. George N. Curzon, M.P. Pp. 83. (London: The Royal Geographical Society.)

WE are glad that this notable contribution to geography has been reprinted from the *Geographical Journal*, and published as a volume handy in size and attractive in *format*. For ages the Pamirs and the Oxus have impressed the imagination of humanity, and though fancy has now to give way to facts, "the mystery and romance of the fabled Roof of the World having been extinguished by the theodolite and the compass, and superseded by the accurate delineation of scientific maps," this celebrated region is full of interest—how full can only be understood by those who read the present monograph, which happily combines historical records with personal experience.

The Journal of the Essex Technical Laboratories. Vol. ii. Edited by David Houston. Pp. 340. (Chelmsford: County Technical Laboratories, 1896.)

A HELPFUL *Bulletin* is published monthly by the Technical Instruction Committee of the Essex County Council. The bulletins issued from October 1895 to September 1896 are here brought together, and published in the form of a handy volume. Notes and articles on most branches of biological knowledge are included in the volume; and also a short course of lessons in elementary chemistry. Many of the articles are well illustrated, and they will all assist in making the agriculturist and horticulturist realise the value of scientific work.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

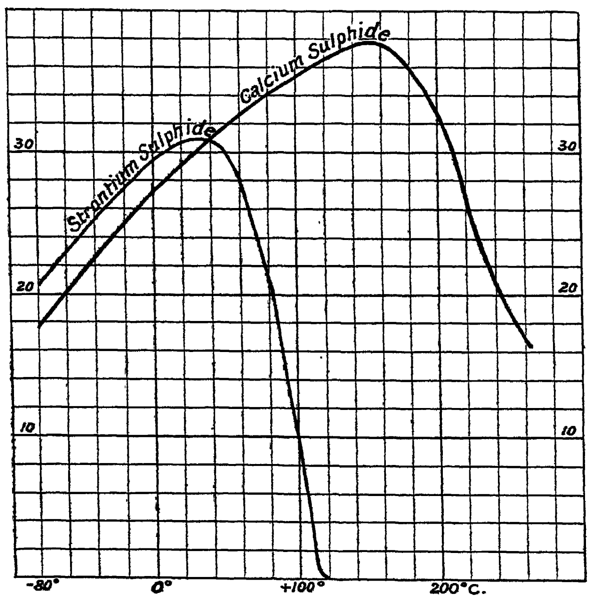
Effect of Change in Temperature on Phosphorescent Substances.

WHEN a substance that possesses phosphorescent properties is exposed to suitable light vibrations, it is found to glow with a certain brightness when the light is shut off.

When such substances are exposed under *similar conditions* for a sufficient length of time the intensity of the phosphorescent light emitted reaches a maximum, which maximum is constant for each substance.

If now the temperature of the substance under observation be altered, the other conditions remaining the same, it is found that the maximum intensity of the light emitted varies with the temperature, and that the maximum for any temperature is constant for that temperature.

The light to which the substances under observation were exposed was that from a spark discharge of a Leyden jar coupled up with the terminals of an induction coil. The instant the spark is stopped, the intensity of the light emitted by the substance is estimated by a photometer devised for the purpose. The principle of the photometer consists in diminishing light



that shines through an aperture of given area, by interposing thin sheets of oil paper. A slip of glass is also interposed, of the same colour as the light emitted by the phosphorescent substance. As yet this photometer has only been used to compare the maximum intensity of the light emitted from the same substance at different temperatures. Now let us suppose, for example, that with a specimen of calcium sulphide at $-40°$ C. ten papers had to be interposed before the light emitted from the sulphide and that from the photometer were of equal intensity; while at 96° C. only seven papers had to be interposed. By taking the reciprocal of the antilog of 10 and the reciprocal of the antilog of 7, we have a rough measure of the relative intensity of the light emitted at $-40°$ and $+96°$ respectively. The antilogs were plotted to scale, and from the curves thus obtained, the accompanying reciprocal curves, showing how the light emitted varies with the temperature, were plotted.

Sinistral Screws.

IF mechanical screws "bear" upon natural spirals, as of the *Gasteropoda* (NATURE, May 27, p. 79), it may be worth while to observe that sinistral forms survive in art, as in nature.

The silversmiths of Western India still commonly use a sinistral screw of very primitive form, a pin with a wire twisted round it, especially in the buckles of silver belts; things of very common wear. Europeans, coming into possession of such jewellery, are often sorely puzzled how to open and shut it. Yet these people are as right-handed as we; and write, as we do, "*with* the sun."

W. F. SINCLAIR.

Luminous Phenomena observed on Mountains.

THE following account of an occurrence somewhat similar to those recently recorded in NATURE may be of interest. I will give it in the observer's (Rev. W. E. Postlethwaite) own words.

"On March 5, at 9 p.m., I was crossing the Towans, wind north-west; a slight shower came on, which lasted about ten minutes. During that time my hat-brim, ferrule of walking-stick, finger-tips, and the edges of a book I was carrying were phosphorescent, the same colour, and in some places as bright, as the light emitted by a glow-worm. The light was the brightest on the windward side."

The "Towans" referred to in the foregoing account are near Helston, Cornwall, on the sea coast, with an altitude ranging from sea-level to 174 feet above, and with a general downward inclination towards the north-west.

Trewirgie, Redruth, May 29. ARTHUR P. JENKIN.

The Designation of Wave-Clouds.

IN a general article on the "Photographic Observation of Clouds," published in NATURE of February 4 (vol. lv. p. 332), you call attention to the wave-clouds, the origin of which was first explained by Helmholtz, and remark that the name of "Wogen wolken" has been suggested as their designation. May I call your attention to a paper I read before the Linnean Society of New South Wales on August 29, 1894, in which the name *undulus* is suggested for the ripple- or wave-clouds. The name has the advantage of falling easily into line with Howard's nomenclature. And some name is necessary, for out of combinations of the elementary forms *stratus*, *cumulus*, *cirrus*, and *undulus* can be derived most of the diversified and ever-changing cloud-groups, which never cease to delight and astonish the eye and mind of man.

A. H. S. LUCAS.

Newington College, Sydney, April 16.

THE BAKERIAN LECTURE.—ON THE MECHANICAL EQUIVALENT OF HEAT.[1]

THE purpose of this research differs essentially from that of any previous research on the mechanical equivalent of heat. In order to diminish the loss of heat by radiation, as well as to obtain the equivalent for water in the neighbourhood of ordinary temperatures, the ranges of temperature over which the previous dynamical measurements have been made are greatly less than the standard interval between the physically fixed points of temperature to which all thermal measures are referred, and so have of necessity involved the use of scales, the intervals of which depend on the constancy of the relative expansions of such substances as glass, mercury, and air. On the other hand, in this research the object has been to determine the mechanical equivalent of the total heat necessary to raise the temperature of water over the standard interval of temperature, and thus to obtain directly the equivalent of the mean specific heat between the freezing and boiling points.

This undertaking is the result of the occurrence of circumstances which afforded an opportunity such as might not again occur. This consisted in the facilities offered by the appliances which formed the original equipment of the Whitworth Engineering Laboratory, in 1888, the more essential of these being an engine of 100 H.P., working one of Prof. Reynolds' hydraulic brakes. This brake maintains any constant moment of

[1] By Prof. Osborne Reynolds, F.R.S., and W. H. Moorby. Read before the Royal Society, May 20. [Abstract.]

resistance on the engine shaft, independent of the speed, all the work done being converted into heat, which appears in the rise of temperature of a steady stream of water flowing through the brake, the magnitude of which stream is independent of the load on the brake or the speed of the engine, and is under independent control.

The existence of the Manchester town's water, of a purity expressed by 3 grains of salts to the gallon, conveniently distributed in the laboratory, as well as auxiliary power, both steam and water.

Although unconsciously, the research was really commenced in 1890, when, without any intention of making a determination of the heat equivalent of the work done on the brake, but solely for the purpose of verifying the mechanical balance of the brake, provision for thermal measurements was added, and a system of trial instituted, in which the object sought was only that of obtaining consistent results over definite portions of the scales of uncorrected thermometers, eliminating the errors resulting from radiation by taking the differences of two trials. In these trials the temperature ranged from 40° to 50° F., and their development was continued over two years. Then it occurred to Prof. Reynolds that by the same method the great facility which this brake was then seen to afford would be available for the independent determination of the mechanical equivalent, if it could be arranged that water should enter the brake at the temperature of melting ice, and leave it at that of water boiling under the standard pressure. Since then all that would be required of the thermometers would be the identification of these temperatures, and with a range of 180° the error in scale over one or two degrees would be comparatively of small importance. At first the difficulties seemed formidable; but on trying by gradually diminishing the supply of water to the brake when it was absorbing 60 H.P., and finding that it ran steadily under control of its automatic gear till the temperature was within three or four degrees of boiling, he further considered the matter, and during the next two years convinced himself of the practicability of the necessary additional appliances by preliminary designs. These consisted of:—

(1) An artificial atmosphere or means of maintaining a steady air pressure of 4/3 atmosphere in the air passages of the brake.

(2) A circulating pump and water cooler, by which the entering water, some 30 lbs. a minute, could be forced through the cooler into the brake at a temperature of 32°, having been cooled by ice from the temperature of the town's main.

(3) A condenser by which the water leaving the brake at 212° might be cooled down to atmospheric temperature before being discharged into the atmosphere and weighed.

(4) Such alteration in the manner of supporting the brake on the shaft as would prevent excess of leakage from the bushes in consequence of the greater pressure of air in the brake, since not only would the leaks be increased, but when the rise of temperature was increased to 180° the quantity for any power would be diminished to one-sixth of that for a rise of 30°, so that any leakage would become six times the relative importance.

(5) Some means by which assurance of the elimination of the radiation and conduction could be obtained, as with a temperature of 140° F. above the laboratory these would probably amount to 2 or 3 per cent. of the total heat.

(6) Scales for greater facility and accuracy in weighing the water with a switch actuated by the counter.

(7) A pressure gauge or barometer by which the standard for the boiling-points might be readily determined at 3° or 4° F. above and below the boiling-point, so as to admit of ready and frequent correction of the thermometers used for identifying the temperature of the effluent water.

(8) Some means of determining the terminal differences of temperature and quantities of water in the brake, which would be relatively six times as large as with 30° rise.

These preliminary designs apparently demonstrated the practicability of the appliances, and also the possibility of their inclusion in the already much occupied space adjacent to the brake. But there remained still much to be done in the way of experimental investigation in order to obtain the data for proportioning the appliances.

In July 1894, Mr. Moorby having undertaken to devote himself to the research, the experiments necessary for the appliances were at once commenced, and these, together with the construction of the appliances and then standardising, and preliminary experiments while this was in progress, occupied till February 1896, when Mr. Moorby commenced the main experiments, which were continued into July 1896.

In these experiments the time of running was 62 minutes; the speed 300 revolutions a minute, on the speed gauges. Observations of speeds, of the temperature of the inflowing and effluent water, and of the temperature of the air were made every two minutes. Observations of the slope of the temperature of the shaft were made every eight minutes.

The temperature of the inflowing water varied from 32·5° to 34°, and that of the effluent from 210° to 214° F. The effluent water was cooled to 8·5° before entering the tank on the scales, in which it was weighed, weighings being taken before and after each trial.

The temperature of the metal surface of the brake being sensibly the same as that of the effluent water (212°), and by taking the difference in the work absorbed in two trials and the differences in the heats developed the errors of radiation and balance in the brake were approximately eliminated, and in order to complete the elimination the coefficient of radiation was approximately determined, so that a correction might be applied for any residual differences of temperature as observed, and in the same way with the slope of temperatures. Further assurance was also obtained by making some trials with the brake naked and others with it covered, so as to reduce the loss of heat to one-fifth; and, in the same way, with every circumstance which could effect the result trials, means were taken to vary the circumstances in different series of trials, so as to obtain an estimate of the limits of error. All the appliances were most carefully standardised; and taking all the limits of error into account the limit of the sum was less than 0·0003.

In all fifty-two trials were included in the final result. Of these—

25	with loads on the brake of	1200 ft.-lbs.	at	70 H.P.
21	,, ,,	600	,,	35 ,,
6	,, ,,	400	,,	23 ,,

From these, twenty-five separate determinations were made of the equivalent, subject to certain general corrections given below, which gave a mean value 777·91, and from this none of the separate determinations differed by as much as 0·2 per cent., which arranged in eight groups, according to the circumstances under which they were made, the greatest divergence from the mean was 0·05 per cent.

It was found impracticable to eliminate entirely from each determination the losses of heat due to radiation, conduction, leakage of water, &c., and so it was found advisable to determine what these losses were. This information was given by the trials themselves, and the necessary corrections were applied to each separate determination. As illustrating the extent to which the method adopted did eliminate these errors, it is interesting to remark that on the mean value of the equivalent determined, without taking these errors into account, the error was only 0·0192 per cent.

Certain final corrections, which had the same values for all trials, were made to the mean value of J, already given. These were introduced on the following various counts :—

I. Length of the brake lever (0·00042).
II. Salts dissolved in Manchester water (0·00003).
III. Air dissolved in water used in the trials (– 0·00021).
IV. Reduction of weighings to vacuo (– 0·00120).
V. Varying specific heat of water (– 0·00006).
VI. Pressure on thermometer bulbs (– 0·00037).
VII. Work done against gravity (0·00007).
VIII. Engagement of counter (0·00001).

Their total effect was to introduce a correction factor of (1 – 0·00125).

The mean corrected value of the specific heat of water between freezing and boiling points, as measured in mechanical units at Manchester, is found to be 776·94.

THE INTERNATIONAL GEOLOGICAL CONGRESS IN RUSSIA.

THE International Geological Congress may be said to come of age this year, for it was founded at Philadelphia in 1876, at a meeting held under the presidency of the veteran James Hall. The first organised session was held at Paris in 1878, and since then meetings have taken place at Bologna, Berlin, London, Washington, and Zürich. The seventh session is to be held at St. Petersburg, with Prof A. Karpinsky as President.

The ordinary meetings of the Congress will be held in the rooms of the Imperial Academy of Sciences at St. Petersburg. There will be a preliminary assembly of the members on August 28, the formal opening will take place on the following day, and the meeting will terminate on September 4. According to the Russian Calendar these dates will be twelve days earlier, namely, August 16, 17, and 23.

The meetings will extend over eight hours. From 9 till 10 a.m. the Committees of the Congress will deliberate ; from 10 till 2 p.m. there will be discussions on questions proposed in the programme of the Organising Committee. One hour is then set aside for visits to museums and to the exhibition of maps, sections, books, specimens and instruments—possibly some members may then take the opportunity of obtaining lunch. From 3 to 5 o'clock papers of a general character will be read, and these will be so arranged that only one branch of geological science will be discussed each day.

The Organising Committee will reopen the subject of the unification of geological nomenclature. The larger divisions of the earth's history must be based on general palæontological characters, and in defining the several systems attention will be specially given to the study of pelagic life and the evidences of organic evolution. In order that a system be well established it must be capable of subdivision into stages characterised by well-marked pelagic faunas, and these should have a European or equivalent value. It is recognised that sub-stages have only a regional value, while minor divisions have but a local character, and with these the Congress does not deal. The divisions, in short, which the assembly will be called upon to discuss are those of geological time, based on the occurrence of successive groups and zones of fossils ; the purely stratigraphical divisions are essentially regional or local, and they may reasonably be left for each country to fix according to its own necessities ; for they are all important in the interpretation of the structure of a district, in determining its economic resources, and in explaining the origin of its scenery. On the other hand, when we seek to trace out the history of the great changes which the earth at large has undergone, the more comprehensive life-divisions are all important ; and these only can be universally applied, and, we hope, universally adopted. It is true that life-divisions are no more to be rigidly defined than are stratigraphical divisions in the rocks, but fossils are the only guides for correlating the formations in countries far apart. There should be no serious disagreement among geologists, at any rate, with regard to the principles of correlation ; and there is no reason why, after full and friendly discussion, a particular nomenclature should not be generally accepted. It need not interfere with our local divisions, any more than great chronological terms, if applied to human history in general, would interfere with our own time-divisions marked by the reigns of successive monarchs.

The Organising Committee will also deal with the subject of petrographic nomenclature, in the hope of reducing the number of terms now used, and of preventing unnecessary names being introduced. In petrology, as in palæontology, one is nowadays in constant need of a dictionary or glossary, or table of synonyms, to understand the various names of rocks or rock-structures and fossils.

The scheme for Excursions in connection with the Congress is an elaborate one. There will be excursions both before and after the ordinary meeting, and those who have time and money will have grand opportunities of visiting many parts of the Russian empire in Europe.

Prior to the Congress there will be three excursions ; namely, to the Ural regions, to Esthonia, and to Finland. The Ural excursion is timed to take place between July 28 and August 27. There will be a general gathering of the party at Moscow on July 29, and those who join are advised to take thick boots, warm clothing, and waterproof cloaks, for there will be rough walking as well as long journeys in open carriages and on horseback. Messrs. Nikitin, Tschernyschew, Arzruni, Karpinsky, and Stuckenberg will act as leaders. The party will take train to Riazan, and thence journeying to Syzran, on the Volga, they will cross Jurassic, Cretaceous, and Tertiary strata. Thence from Samara to Oufa, Permian and Triassic rocks will be traversed, while onwards to the Ural mountains the party will pass over Carboniferous, Devonian, and Siluro-Cambrian strata, which present evidences of considerable metamorphism, and which, together with various schists, are penetrated by numerous eruptive rocks. The region is famed for its metalliferous deposits, and various mines in rocks bearing gold, copper, and manganese will be visited, as also will be the Imperial stone-cutting works at Ekatherinebourg. The return journey will be made by Perm, Kazan, and Nijni-Novgorod.

The excursion into Esthonia (August 13 to 27) under the direction of M. Schmidt, will be by rail to Reval on the Gulf of Finland, and then a visit will be paid to the Isle of Dago, when attention will be given to the fossiliferous Upper and Lower Silurian rocks.

The excursion to Finland will be made under the guidance of M. W. Ramsáy. The members will assemble at Helsingfors on August 21, and return to St. Petersburg on August 28. Tammerfors and Lavia will be reached, and attention will be directed to the glacial phenomena and the various crystalline rocks.

After the meeting of the Congress is over, the principal excursion will be to the Caucasus, leaving St. Petersburg on September 5, and arriving at Moscow on the following day. The excursion party will then be divided into three sections, A, B, and C. Section A will be conducted by Messrs. Nikitin, Gourow, Tschernyschew, Loutougin, Rouguéwitsch, and Konchin. Leaving Moscow, and travelling by Podolsk, the route will be over Jurassic, Carboniferous and Devonian rocks, and on to the Cretaceous strata of Koursk and Kharkow. Thence the

party will proceed to Rostow, at the head of the Sea of Azov, examining a mercury-mine and certain mineral springs, and ultimately reaching Wladikavkaz, on the northern side of the Caucasus mountains. Section B will start, under the guidance of Messrs. Pavlow and Amalitzky, from Moscow to Nijni-Novgorod, across Jurassic and Triassic formations to the Cretaceous rocks of Simbirsk on the Volga. Journeying southwards they will visit asphalt quarries, and by means of steamer and railway they will proceed along the plains of the Volga and the borders of the Kirghiz Steppes to Astrakhan and Wladikavkaz. Section C will be under the direction of M. Sokolow, and will journey to Kiew on the Dnieper, paying especial attention to the Tertiary and Post-Tertiary deposits. Following the river to Alexandrovsk, the party will ultimately join the two other sections at Wladikavkaz by way of Rostow.

Thus united the whole party will proceed across the mountainous country to Tiflis, under the direction of M. Loewinson-Lessing, some few members separating for a while to examine a glacier under the guidance of M. Kolenko. Tertiary, Cretaceous, Jurassic, and metamorphic rocks will be seen. From Tiflis all will proceed to Bakou, on the borders of the Caspian, and thence separating into two portions, they will traverse the mountainous region from east to west, and unite again at Rion. Some may spend a week in the Caucasus, examining the Mamisson glacier; others will have an opportunity of visiting Mount Ararat.

Those who desire to still further continue their field-studies among Cretaceous and Jurassic rocks, may take part in a general excursion into the Crimea. They will proceed by steamer from Batoum to Kertch, and eventually, on October 5, there will be a reunion of all the remaining excursionists at Sébastopol. Thus will terminate the great programme of expeditions planned by the geologists of Russia. H. B. W.

THE NEW LABORATORIES AT GUY'S HOSPITAL.

THE new laboratories which have been erected at Guy's Hospital at the expense of the staff of the medical school, and have entailed an expenditure of about 12,000*l*., were opened by the Prince of Wales on Wednesday in last week. The buildings occupy about one-third of the whole structure which is contemplated, and a further sum of 35,000*l*. will be required to complete the scheme. The entire building is designed to provide under one roof all the accommodation required by the school in all branches of the medical curriculum. The part of the building now opened contains a well-arranged lecture theatre capable of seating four hundred persons, and beneath it are three dark rooms. The first of these is designed for the reception of the spectrophotometer, polarimeter, and spectroscope, for the use of those engaged in work with them. The other two rooms are intended for galvanometric and photographic work. Other parts of the building are occupied by the laboratories and preparation room for physiological and pathological chemistry, a balance room, a calorimeter room, and a gas room. On the top floor the whole of the front of the building is devoted to the laboratory and preparation room for normal and morbid histology. Large classes can be accommodated, and the claims of investigation have received ample consideration.

An address of welcome was read to the Prince of Wales by Mr. Howse, the senior surgeon, and Dr. Pye-Smith, senior physician, described the objects of the new building in the following words :—

Your Royal Highnesses, my Lords, Ladies, and Gentlemen,—I have been asked by my colleagues, the lecturers, demonstrators, and tutors of this school of medicine to state very shortly the use and object of the building in which we stand.

While in every civilised country, except England and the United States, the training of physicians and surgeons is provided for by the Government as part of its duties, here the profession provides for itself and for the public. The schools of medicine in London have formed themselves around the great hospitals, and have only gradually acquired their present importance and repute.

Apart from practical instruction in the wards of the hospital, some knowledge of natural science has always been included in the preparation for this liberal profession. Physicians have always been botanists and chemists, surgeons have always been anatomists; nor need we look far for proofs that the highest attainments in scholarship and mathematics are admirable training for pathology.

During the last sixty years, great has been the development of these preliminary scientific studies, the indispensable foundation of rational, honourable and helpful medicine. We have now not only able lecturers on physics, on chemistry, and on biology, but well-equipped laboratories for each of these subjects, in which our students become practically familiar with scientific facts. We have twice rebuilt or greatly enlarged our museums and laboratories for *physiology*, for *clinical chemistry*, for *histology*, and for the new science of *bacteriology*. But, again, as our numbers increase and the progress of science goes on, we must pull down our barns and build greater. In medical science, as in a still more important discipline, the Augustinian saying is true, *Qui satis dixerit, perditus est.* We must go on, if we are not to fall back.

Accordingly, after repeatedly considering various plans for enlarging and remodelling the old museum and laboratories, we determined that none of them were satisfactory; and that we must erect a new building for the important department of physiology; one not comparable to the magnificent palaces which are called "Institutes" at Berlin and Strassburg, but such as may rank with the laboratories of our friendly rivals, St. Bartholomew's, St. Thomas's, and the other schools of London, of Cambridge, and of Edinburgh, fitted for the best possible teaching and the most advanced researches.

This part of the future range of museums and class-rooms is now completed. Immense labour has been bestowed upon it. Similar laboratories in this kingdom, and on the continent, have been visited and studied by our lecturers, and the result is what we have every reason to believe will be sufficient for another fifty years. Two names among many to whom we are deeply indebted demand particular mention—those of the architect, Mr. Woodd, and of Dr. Shaw, the Dean of the Medical School.

It is only right to explain how the necessary funds were raised.

We all know the grievous deficiency of rents which have compelled the Governors of Guy's Hospital to close some of their wards.

We know too, and shall never forget, how you, Sir, came to their help, and how, by your generous and practical aid, the prospects of further crippling of the charity were banished, and replaced by a hope that some day its closed wards might be reopened to the public.

The treasurer of the hospital could not give, and the medical school could never ask for, help from the hospital funds. Every pound given to Guy's Hospital is devoted to the direct relief of the patients. The school does not receive from, but gives to the hospital, with which its prosperity and almost its existence are united.

It is needless to say that the Government does not help medical science as it does on the continent, and our rich men are only beginning to learn to devote their wealth to founding colleges and laboratories and observatories, like those which do honour to our kinsmen across the Atlantic.

Only one resource remained open: we determined to appeal—to ourselves. We made a collection; all giving something as he was able, and with the money thus subscribed this physiological institute was built.

Here physiology will be zealously and efficiently taught, and fresh knowledge will be acquired. The old laboratories, where Sir Wm. Gull, Dr. Pavy, Mr. Golding Bird, and the late Dr. Wooldridge worked, will hand over a good tradition of industry, intelligence, and zeal to their successors, and the benefit will not be only for our students, but for the whole community.

Such institutes are too few; for they are not only "light-bringing, but fruit-bearing." They not only form the foundation of scientific and efficient treatment of disease, but are the source whence spring such discoveries as bless the whole world, and crown with the gratitude of nations the names of Jenner, of Simpson, of Pasteur, and of Lister.

One of our kings, sir, zealously helped forward Harvey's immortal work on the movements of the heart and of the blood; another founded the Royal Society, "to search out the secrets of nature by way of experiment."

To you, therefore, as a patron of all that tends to the increase of knowledge and the relief of suffering, we turn and ask your Royal Highness to open this laboratory.

In Harvey's words: *Ad viliorum animalium inspectionem cum Heraclito apud Aristotelem introire si vultis, accedite, nam neque hic Dii desunt immortales.*

The Prince of Wales then declared the building open, and, in the course of a short address, he is reported by the *Times* to have said:—I understand that the building which I have just declared open is to be used in great part for the study of those sciences which have for their object the observation of the natural laws of life. It was in such observations that your distinguished physician, Sir William Gull, first won renown. Nor is it possible to over-estimate the value of such work in the investigation and treatment of disease. One thing I would venture to impress upon our students—namely, that, in endeavouring to follow in the footsteps of the great and good men whom Guy's delights to honour, they should cultivate that gentle and humane spirit which, not confined to any one school, is the best possession of the medical faculty. I have made careful inquiries, and have every reason to believe that whenever experiments upon animals are performed in this school they are undertaken with the object of promoting advances in medicine and surgery which are likely to be of benefit to suffering humanity, and I have satisfied myself that such experiments are conducted under strict supervision, by highly qualified investigators, and that in practice the only operations performed upon animals which are not in a condition of complete anæsthesia are inoculations and hypodermic injections. Looking back upon the history of this school, one cannot but admire the wonderful powers of observation which enabled such men as Astley Cooper, Bright, Addison, Hodgkin, and Gull, with but slender aid from scientific apparatus, to add so largely to the sum of human knowledge. I need hardly remind you that more than one of these great workers in your profession has had his name perpetuated in connection with the discoveries he made in the wards of Guy's Hospital—discoveries which paved the way for the more enlightened treatment of some of the most frequent, and yet most fatal diseases to which man is subject. That harvest has been gathered, and for the present and future generations it remains, with more exact appliances and more delicate apparatus provided by the sister sciences, to seek on other fields to emulate their illustrious predecessors' example. To this end are needed ampler buildings, specially designed rooms, and complicated mechanical contrivances, all of them involving additional expenditure. Your senior physician has made it clear to all how, relying upon themselves, the staff of the medical school have erected this building. I may be permitted to emphasise the fact, to which Dr. Pye-Smith has alluded, that the present building is but an instalment of a more extensive design which is to be completed as soon as funds are forthcoming. I would venture to express a hope that this day may not be long delayed, and that when the building is completed, room will be provided to adequately display the unique collection of wax models which so much interested me when first I visited your museum. The medical staff have expended as much as they safely can, and it is to men of wealth and philanthropic aspirations that we confidently look for further assistance. Let such men once realise that money given for the purposes of medical education directly benefits humanity, and I cannot doubt that that spirit, which has prompted the British people to provide by voluntary effort what in other countries is provided by the State, will prove effective in the present need. On you students of medicine—and a medical man, as Dr. Wilks has said, should be a student till he dies—it devolves so to order your life's work that you make the best use of the improved opportunities thus provided, and to take care that the great profession to which you have aspired to belong shall, when you leave it, stand as high in the service and in the affection of the public as it does at the present time.

NOTES.

THE Select Committee of the House of Commons appointed to inquire into the administration of the museums of the Science and Art Department has presented an interim report calling attention to the peril of destruction by fire to which the collections at the South Kensington Museum are exposed. After describing the general character of the buildings and their inflammable structure, the Committee conclude their report with the following observation:—"This necessity of providing buildings suitable for the exhibition of the objects of art and science collected at South Kensington has been long under the consideration of successive Governments. Your Committee regard it as their immediate duty to lay before the House of Commons by means of an interim report their very strong opinion that permanent buildings for the adequate accommodation of the collections at the South Kensington Museum should be proceeded with without delay. They are of opinion that it will be a source of grave discredit to the country if the settlement of this matter, which has been the subject of consideration by Government for many years, and of endless correspondence between the departments concerned, is any longer delayed."

THE Paris correspondent of the *Times* reports that at Monday's sitting of the Academy of Sciences, M. Moissan communicated the results of his experiments with Prof. Dewar on the liquefaction of fluorine gas. M. Moissan announced that the gas had been liquefied at about 185° C. below zero. When a current of fluorine gas is passed into an apparatus maintained in the midst of liquid oxygen in tranquil ebullition at a temperature of −180° C., liquefaction does not occur. But as soon as that temperature is diminished by exhausting the gas above the liquid oxygen, the liquefaction of the fluorine begins, and a clear yellow and extremely mobile liquid is obtained, which resumes the gaseous state as soon as the temperature rises. This liquid has lost the chemical activity characteristic of fluorine in a state of gas. It no longer attacks glass, silicon, sulphur, or phosphorus. Fluorine at a very low temperature, however, still attacks carburetted hydrogen, and its affinity for hydrogen seems still to exist.

JUST too late for insertion in last week's NATURE we received a cablegram from Prof. A. B. Macallum, Local Secretary for the forthcoming meeting of the British Association at Toronto, asking us to urge members of the Association to apply for Canadian Steamship berths as soon as possible, as the berths still remaining will soon be filled.

SIR ARCHIBALD GEIKIE had a hearty reception from geologists in America during his recent visit. The number of *Science* which has just reached us contains a long article, by Prof. J. F. Kemp, upon the visit of the distinguished director of our geological survey, and it is evident from the account that geologists in America regarded the occasion as one of exceptional interest. Sir Archibald Geikie crossed the Atlantic to open a new course of lectures on geology, founded in connection with the Johns Hopkins University, Baltimore, by Mrs. G. H. Williams. The purpose of the foundation is to support an annual course of lectures in geology, to be given alternately by European and American geologists of distinction; and the fact that Sir Archibald Geikie was chosen to deliver the first course is a high compliment to his learning, as well as a testimony to the breadth of his sympathies. Before he arrived in America, invitations were sent by the Johns Hopkins University to geologists throughout the country, asking them to be present, and to take part in the excursions which had been arranged. In response, fifty or more leading geologists in America accepted. While the lectures were being delivered, short excursions were conducted almost daily to places of

geological interest near Baltimore, on one of which Sir Archibald Geikie and his companions were the guests of the Secretary of the Navy at the Naval Academy, Annapolis, and upon one of the United States Government vessels on a trip to view the Cretaceous and Tertiary formations along the Severn River. A longer excursion was made at the close of the lectures, so as to illustrate the geology of the State of Maryland. Through the efforts of Prof. W. B. Clark, who is also State Geologist of Maryland, the interest of the Governor of the State and of the principal railway and mining officials had been secured, so that free transportation was given on the Baltimore and Ohio, the Cumberland and Potomac, and the Western Maryland Railways, as well as on one of the State official steamboats. Before breaking up, the entire company of geologists signed and presented a short address of thanks to the Board of Commissioners of the Maryland Geological Survey and the State Geologist, for the hospitable forethought which had enabled them to spend four days in inspecting a region presenting so many interesting geological aspects. At the close of the Baltimore visit Sir Archibald Geikie went to Washington, where he delivered an address before the Geological Society, and was afterwards given a reception in the rooms of the U.S. Geological Survey. He also gave addresses to the students of Bryn Mawr College, the Philosophical Society in Philadelphia, and the Brooklyn Institute. The different institutions seemed to vie with one another in doing honour to their guest; and it is to be hoped that when an opportunity arises, the cordial feeling thus manifested will be fully reciprocated. Sir Archibald Geikie returned to London a few days ago. His lectures at the John Hopkins University will ultimately be published.

WE regret to hear that Dr. Fritz Müller, the well-known biologist, died at Blumenau on May 21.

A BILL to legalise the use of weights and measures of the metric system was given a first reading in the House of Commons on Thursday last.

AN afternoon meeting of the Anthropological Institute will be held on June 15, at the South Kensington Museum, when Mr. A. P. Maudslay will lecture on "The Maya Monuments and Inscriptions in Central America."

IT is announced that the memorial to Joseph Thomson, the African explorer, will be unveiled by Sir Clements Markham, K.C.B., F.R.S., at Thomson's native town, Thornhill, near Dumfries, on Tuesday next, June 8.

THE great lens for the Yerkes telescope has just been finished by the Clarks, at Cambridgeport, and shipped to the University of Chicago, where it will be immediately mounted, as the tube and connected apparatus are already in position.

IN reply to a question asked in the House of Commons on Friday last, whether any steps had been taken to fix the site of the new magnetic observatory at Greenwich, the First Commissioner of Works replied that a site had been selected, with the concurrence of the Astronomer Royal.

A NEW biological station at Millport, on the Clyde, was opened a few days ago (says the *British Medical Journal*) by Dr. John Murray, F.R.S. The station has been erected at a cost of 1500*l.*, and though in regard to accommodation and equipment it cannot compare with many similar institutions in this country and the continent, as Dr. Murray pointed out, its position makes it a place of very great possibilities. The collection of the late Dr. Robertson, who did so much for the station, has been presented by his wife for the museum of the building.

THE State recognition given to the International Congress of Medicine and Surgery, to be held in Moscow in August next, is referred to in the *Lancet*. The Czar has taken the Congress under his patronage, and has consented to receive deputations from the various nationalities represented at the Congress. It is probable that the reception will take place in St. Petersburg immediately after the close of the meetings in Moscow. The Russian Government has acted most liberally towards the Congress. It has increased its original grant of 50,000 roubles towards the expenses by an additional grant of 25,000. This makes the handsome total of 75,000 roubles, or about 8000*l.* at the present exchange. In addition to this, the State has promised free railway tickets to members of the Congress from the frontier to Moscow and back. To Russian members similar free tickets will be granted from any part of the empire. Just as liberal recognition has been given by the Russian Government to the International Geological Congress to be held at St. Petersburg at the end of August.

IN connection with the recent correspondence in these columns on luminous phenomena observed on mountains, it is interesting to direct attention to a very remarkable series of observations of electrical storms on Pike's Peak, Colorado, contained in vol. xxii. of the Annals of the Astronomical Observatory of Harvard College, and described in NATURE (vol. xliii. p. 595, October 16, 1890). Luminous jets appeared very often along the telegraph wires for the length of an eighth of a mile, and the anemometer cups looked like revolving balls of fire. Upon touching the anemometer under these conditions, an observer found "his hands instantly become aflame. On raising them and spreading his fingers, each of them became tipped with one or more cones of light nearly three inches in length." Many more striking effects of this character are described in detail in the report to which reference has been made.

THE Smithsonian Institution is publishing in their "Miscellaneous Collections" a number of interesting memoirs submitted in the Hodgkins Fund Prize Competition. No. 1077 of this series is a contribution by Mr. A. McAdie, on the equipment and work of an aero-physical observatory, in which he deals especially with the question of future research in connection with our knowledge of atmospheric air and the prevision of weather. After the experience of twenty-five years, the author asks, "Has the synoptic map realised the expectations of meteorologists, and justified the expense of its existence?" The answer is in the affirmative; but if the further question is asked whether the forecaster of to-day is far in advance of the forecaster of 1870, the reply is uncertain, and the experience of recent years would seem to indicate that we have nearly exhausted the capabilities of the weather map in its present form. An aero-physical laboratory would afford opportunity for important research and investigation, and the author draws attention to some profitable lines of study bearing upon the conditions which control the weather. Among such investigations, Oberbeck's papers on the "Motions of the Atmosphere," and von Bezold's "Thermodynamics of the Atmosphere" may be mentioned as examples of the lines indicated. The study of atmospheric electricity also offers possibilities of great extension of our knowledge of atmospheric phenomena. In 1752 a simple experiment demonstrated the nature of the lightning flash, but at the present time the origin of the electricity of thunder-clouds, and similar questions, are as the nature of the lightning was before the time of that experiment. Much useful scientific work in weather forecasting has undoubtedly been done, but it remains none the less true that the present condition of our knowledge is still unsatisfactory.

IN the House of Lords on Friday last, Lord Stanhope moved —"That her Majesty's Government should be invited to take such further steps as are necessary under the Finance Act, 1894–96, to preserve in the country 'such pictures, prints, books, manuscripts, works of art, and scientific collections, not yielding income, as are of national, scientific, or historic interest.'" Speaking upon the subject of the motion, Lord Kelvin pointed out its great importance so far as scientific collections were concerned. It might have an exceedingly injurious effect upon scientific investigation in this country if the heavy death duties were charged upon apparatus for scientific research or upon natural history collections, the property of private owners. Very large sums of money had been spent on private observatories. A large part of the astronomical investigation in the United Kingdom had been performed by amateur astronomers, if he might use the word, who stood at the very head of scientific men in respect of knowledge and skill in scientific investigation. A large amount of money had been spent upon private observatories, on great telescopes, and on other instruments of research, which would be subject to exceedingly heavy death duties, and the heirs of the proprietors might find it impossible to keep them. The result might be that it would be necessary to sell them; foreign purchasers might get them, and those valuable tools for scientific work might be sent out of England and leave this country so much the poorer in respect of scientific work. The same might also be said of natural history collections. Such collections were of unique value. A man might spend his whole life in the work of making such collections and leave something that was of priceless value in reality, and which would be estimated at a very high money figure if the expense involved in creating the collection was to be taken into account. It would be most disastrous that such natural history collections or apparatus for scientific investigation should be subjected to the severe death duties that were charged on those to whom was left property which they could use, and which might be sources of income and revenue to the inheritors, when that which was inherited could only be of use through the inheritor devoting himself, as the creator of the collection had devoted himself, to the public good and for the advancement of science. He thought it would be exceedingly bad, and in every way undesirable that a duty anything more than merely nominal should be charged in such cases.—Lord Cross explained that there was a great desire on the part of the Chancellor of the Exchequer to deal fairly with this matter. Anything that could be done within the terms of the Act of Parliament would be done by him to keep works of art, whether they be pictures, manuscripts, scientific collections, or scientific instruments, in the country. He hoped, therefore, that the motion, with the main object of which the Government fully sympathised, would not be pressed. The motion was afterwards negatived without a division; so the decision whether the objects referred to shall be liable for estate duty or not, remains with the Chancellor of the Exchequer.

A VERY valuable address on the progress of medicine in the Victorian Era, delivered on May 27 by Mrs. Garrett Anderson, M.D., before the East Anglian Branch of the British Medical Association (of which branch she has been elected President), concluded with the following clear statement of the directions in which advances may be gained by research. "It is in medicine proper that more light is specially needed. We want, in medicine, more of the knowledge that can only be gained through research. We want to know the real nature of malignant growths, the complete life-history of the bacillus of diphtheria, of the parasite of malaria, the conditions they require, and how to produce immunity from them and from tuberculosis. It does not need much imagination to realise how the world would be helped, and its sorrows lightened, if cancer, consumption, and diphtheria could be brought under control in at all the same measure as small-pox, thanks to Jenner, has been brought; nor how civilisation would advance by leaps and bounds in many parts of the world if malaria could be effectually combated. Victory in these directions can only come through patient and laborious research, and we should all do our best so to educate public opinion that the true value of this work should be generally recognised, and that the demand for it should no longer be restricted within the narrow limit of the world of science."

PROF. KOCH's final reports upon his rinderpest investigations at Kimberley, appear in the Cape Town *Agricultural Journal* of April 1. The following extracts from the last report, dated March 22, are of interest:—"I consider my researches, respecting the rinderpest, finished in the main, and I believe that I can leave the further working out of them to Dr. Turner, who will for some time still have the assistance of Dr. Kohlstock, and later that of Dr. Kolle, should it be possible to arrange this. This ensures the continuity between my work hitherto and the further investigations at the experimental station. What I had been able so far to find out regarding the microbe of the rinderpest seemed to me too uncertain to mention in my reports. But I have shown Dr. Turner everything I have found in this respect, and he will try to gain further facts about the occurrence and habits of these microbes which, at any rate, do not belong to the class of Bacteria. The discovery that by injection of gall taken from rinderpest animals, sound animals may be protected against rinderpest, and that this discovery is also practically applicable, I consider absolutely proved in view of the results achieved on the farm 'Susanna.' Should my hopes respecting the artificial production of rinderpest-gall by mixture of gall and rinderpest-blood, about which I am not quite certain at present, not realise themselves, it will still be possible to obtain any desired quantity of effective gall by infecting a proportional number of cattle with rinderpest blood and killing them on the sixth or seventh day of the illness. The use of gall for immunisation seems at present to me to be so far superior to immunising with serum, that I would advise the latter procedure to be applied only experimentally."

PROF. J. A. HARPER's paper "On Nuclear Division and Free Cell-formation in the Ascus," reprinted from Pringsheim's *Jahrbücher*, completes a valuable series of observations on the obscure process of nuclear fusion which takes place immediately before the formation of the spores in many of the Ascomycetes. The author does not take the view of several French observers, that this fusion of nuclei is of a sexual character.

THE *Bulletin of Miscellaneous Information*, issued by the Superintendent of the Botanic Garden, Trinidad, mentions the very interesting circumstance that in that island a species of *Bauhinia* (*B. magalandra*, n. sp.), belonging to the Leguminosæ, is pollinated by the agency of bats, the first instance recorded of a "mammalophilous" flower. On visiting a flower the bat alights upon and holds fast to the protruded stamens, and attacks the erect and curved petals. The object of the visit of the bats appears to be not any nectar secreted by the flower, but the insects which are attracted to it by its odour. The flowers open only in the evening.

TOWARDS the end of the notice of vol. ii. of the Cambridge Natural History, in our issue of April 29 (vol. lv. p. 610), reference was made to the admirable illustrations, and regret was expressed that the name of the artist did not appear to be given. We are glad to be able to say that the artist was Mr. Edwin Wilson, of Cambridge, whose illustrative work has taken a high place in science for some years. The volume lately reviewed was written by several different contributors, and, as

there was no preface, the editors were unable to say how very much it owed to Mr. Wilson's skill and care.

To the list of cave animals which appears in Dr. A. S. Packard's monograph in the "Cave Fauna of North America" must now be added seven forms which are new to science, and several forms which, while known, have not hitherto been definitely reported from Mammoth Cave, Kentucky. This new material is described by Dr. Ellsworth Call in the *American Naturalist* (May). The specimens described are very minute, and this fact is in itself sufficient to explain their late appearance in lists of the cave fauna. The paper is a noteworthy contribution to a knowledge of the life of the most interesting cave on the American Continent.

A REPRINT from the *Transactions* of the New York Academy of Sciences gives an account of the results obtained by an expedition to Puget Sound, organised by the Department of Zoology of Columbia University in the summer of 1895. The party consisted of six members, under the leadership of Dr. Bashford Dean. Their main object was to obtain materials for the study of the development of the Chimeroid fish *Hydrolagus*, and eggs and young of the Myxinoid form *Bdellostoma*, both known to be abundant there. In both these respects success was achieved, and large collections of other groups of marine animals were secured for future study.

AMONG noteworthy articles which have come under our notice during the past few days are the following:—Dr. R. W. Shulfeldt points out, in the *Photogram* (June), that many of the figures throughout zoological literature are very frequently anything but correct, depicting often the subject in impossible attitudes, badly proportioned, and with erroneous portrayal of characters. To assist in the improvement of this state of things, he describes how photography should be called in with the view to secure pictures of living animals for reproduction by photographic processes.—The *Century Magazine* for May contains three well-illustrated articles on the construction and use of kites for meteorological and photograph purposes. In the June number of the same magazine, Mabel L. Todd describes the establishment and work of the Harvard College Observatory.—An address on "The Problems of Astronomy," delivered by Prof. Simon Newcomb at the dedication of the Flower Observatory, University of Pennsylvania, is printed in *Science* of May 21.

SOME further details, of great interest as to the fermentation of sugar in the absence of yeast-cells (see NATURE, March 11, p. 442), are given in the current number of the *Berichte* by Buchner. The active extract of yeast very rapidly loses its power of producing fermentation, owing probably to the presence of peptic enzymes. The activity of the solution is not affected by the presence of antiseptic substances, and the solid residue left on evaporation at a low temperature is found to yield an active solution, even after having been kept for nearly three weeks. These facts seem to definitely prove that the fermentation in these cases is not brought about by living protoplasm in any form, but is really due to the substance which the author has termed zymase. This is further confirmed by the fact that dried yeast which has been heated at 100° for six hours, and is incapable of further development, still yields an active solution when treated with sterilised 37 per cent. sugar solution.

THE additions to the Zoological Society's Gardens during the past week include a Chimpanzee (young) (*Anthropopithecus troglodytes*, ♀) from West Africa, presented by the Hon. Sir W. Grantham; a West African Sheep (*Ovis aries*, var. ♂) from West Africa, presented by H.E. Colonel F. Cardew, C.M.G.; a Broad-snouted Cayman (*Caiman latirostris*) from South America, presented by Mr. C. L. Hutchings; an Olive-brown Snake (*Phrynonax fasciatus*) from Trinidad, presented by Mr. R. R. Mole; a Pleasant Antelope (*Tragelaphus gratus*, ♂), four Royal Pythons (*Python regius*) from West Africa, thirteen Cunningham's Skinks (*Egernia cunninghami*), two Punctulated Tree Snakes (*Dendrophis punctulatus*) from Australia, deposited; an Alpaca (*Lama pacos*, ♂) from Peru; two Red-topped Amazons (*Chrysotis rhodocorytha*), three White-eared Conures (*Pyrrhura leucotis*) from Brazil, purchased; two Japanese Deer (*Cervus sika*, ♂ ♂), a Red Deer (*Cervus elaphus*, ♀), a Burrhel Sheep (*Ovis burrhel*, ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE ROTATION PERIOD OF JUPITER'S SATELLITE III.—Mr. Douglass has quite recently determined the period of rotation of Ganymede, Jupiter's third satellite, the period being given as 7 days, 5 hours (Kiel Telegram). This satellite is the brightest and largest of them all, and its sidereal revolution is 7 d. 3 h. 43 m., so that the period of rotation is practically the same as the time of its orbital revolution. This observation partly corroborates what Herschel concluded in 1797, namely, that, like our moon, all the satellites of Jupiter turn the same face towards their primary, thus always presenting to us, when in the same relative situations, the same obscure or brilliant sections of their globes. Engelmann's researches in 1871, and C. E. Burton's, two years later, made this statement of Herschel's almost certain regarding the outer satellite, and since that time it has always seemed probable that it would also apply to the other three. This new observation of Mr. Douglass shows that the deductions of the earlier observers were not very far from the truth.

Referring to this satellite in 1893, Prof. W. H. Pickering (*Astronomy and Astrophysics*, vol. xii. p. 199) said: "On account of its size and brightness, this is much the easiest satellite to observe. Indeed, even the occasionally elliptical shape of its disc has been noted by Lassell, Secchi and Burton. . . . Like our moon, therefore, its period of rotation coincides, at least approximately, with that of its revolution in its orbit. . . . Its surface markings are readily seen, especially during transit, the most conspicuous being a dark belt situated in the northern hemisphere, and inclined about fifteen degrees to its orbit."

AUTOMATIC PHOTOGRAPHY OF THE CORONA.—The idea of connecting several different kinds of instruments with some sort of central automatic arrangement by which one man may work them all during a total eclipse of the sun, is not new; but weather conditions have up to the present prevented any trial being made at the time of an actual eclipse. Mr. David P. Todd, who for the past few years has given considerable attention to this question, describes in the current number of the *Astrophysical Journal* (No. 5, vol. v.) the special automatic shutter and electric commutator which was devised for the Amherst Eclipse Expedition of last year, but which was, unfortunately, not used owing to the bad weather. In all twenty photographic instruments would have been worked by an automatic system, which would have given more than four hundred exposures with several types of reflecting and refracting telescopes, photographic doublets, a pair of spectroscopes, photometers, and a pair of polariscopes.

The system which Mr. Todd advocates is an electric system of control, and he has found that it is perfectly competent to operate any available number of eclipse instruments adapted for photographic purposes; it further makes the time record of every automatic movement in a form which can be identified.

It would be difficult to give the reader a clear idea of this arrangement without the medium of an illustration; so that we refer him to Mr. Todd's article for detailed information.

THE GEGENSCHEIN OR ZODIACAL COUNTERGLOW.—In some former numbers of the *Astronomical Journal* (*A. J.*, vii. 186, xi. 19, and xiii. 169), Prof. Barnard contributed his observations of this phenomenon as seen at the Lick Observatory. His communication to a more recent number (No. 403) of the same journal contains some further observations of considerable interest made at the Yerkes Observatory. He

points out that although these naked-eye observations are subject to a more considerable personal error than if they could have been made with any kind of instrument, yet the determination of the position of this phenomenon depends to a great deal on the experience of the observer. The best method he suggests for its location is to estimate the distance of its centre from the nearest fixed star, and then to identify the star by a chart or an equatorial pointing; by this means he can ordinarily determine the centre to within one degree. Any attempt, he says, to locate its position by tracing the outlines among the stars can only lead the observer to very crude results. Prof. Barnard's observations have indicated that the Gegenschein seems subject to periodical changes in the first parts of October and April; but the weather this year did not permit of a corroboration of this statement. The present observations show that this phenomenon has a north latitude as formerly, and that there is still a tendency to lag in longitude; that is, its longitude is not exactly 180° greater than that of the sun. The following summary shows the results for the last fourteen years:—

Dates.	Lat.	Diff. Long. (λ - ☉)	No. Obs.
	°	°	
1883-1887	+0·4	179·4	16
1888-1891	+1·3	179·4	16
1893	+0·5	179·6	22
1894-1897	+0·4	179·9	11

It may be stated that the difference in longitude for the last four years given above is rather high, owing to the fact that the three observations of 1894 made the difference greater than 180°. Those for 1895 and 1897 gave a value considerably less than 180°.

PERIODIC VARIATIONS OF RAINFALL IN INDIA.

THE meteorology of India during the past five years, 1892-96, has been characterised by the largest and most marked periodic variation of rainfall during the past fifty years at least, and probably for a much longer period. The late Mr. Blanford's monograph on the rainfall of India (page 15) gives a brief statement of the method he adopted for ascertaining the average rainfall of India, year by year, and the normal average. According to this method the mean normal annual rainfall of India is, very approximately, 41 inches. The following gives a comparison of the actual mean rainfall of India with the normal mean for each year from 1875 to 1896, determined by Mr. Blanford's method.

Year.	Mean actual Rainfall.	Variation from normal.	Percentage variation.
	Inches.	Inches.	
1875	43·47	+ 2·38	+ 6
1876	36·60	- 4·49	- 11
1877	36·81	- 4·28	- 10
1878	47·43	+ 6·34	+ 15
1879	42·78	+ 1·69	+ 4
1880	39·53	- 1·56	- 4
1881	41·19	+ 0·10	0
1882	43·73	+ 2·64	+ 6
1883	40·97	- 0·12	0
1884	42·82	+ 1·73	+ 4
1885	42·14	+ 1·05	+ 3
1886	44·11	+ 3·02	+ 7
1887	43·51	+ 2·42	+ 6
1888	39·55	- 1·54	- 4
1889	43·50	+ 2·41	+ 6
1890	41·77	+ 0·68	+ 2
1891	37·55	- 3·54	- 9
1892	46·18	+ 5·09	+ 12
1893	50·16	+ 9·07	+ 22
1894	47·56	+ 6·47	+ 16
1895	38·90	- 2·90	- 7
1896	36·26	- 4·83	- 12

The preceding data indicate that from 1876 to 1891 the annual rainfall of India varied somewhat irregularly and by less than 10 per cent. from the normal with one exception, viz. during the period 1876-78. The meteorological features of this period were very remarkable (*vide* NATURE, vol. xxi., page 477, "On the barometric see-saw between Russia and India in the sun-spot cycle," by H. F. Blanford), the most noteworthy being the drought and famine in Madras in 1876, and the scanty rainfall in North-western India in 1877, which gave rise to considerable suffering. Mr. Blanford subsequently traced the cause of the deficient rainfall in North-western India in 1877 to conditions and actions resulting from excessive snowfall in the Himalayan region during the winter of 1876-77.

The causes of the drought in Mysore and the Madras and Bombay Deccan in 1876, have as yet not been fully ascertained. The snowfall of the winter of 1875-6 was unusually scanty in the North-western Himalayas, although there was a heavy local fall in March and April in a part of the Kashmir Himalayas. The Madras drought and famine was probably due to more general actions and conditions than the winter Himalayan snowfall.

The present meteorological period of abnormal conditions and rainfall it will, however, be seen is not only more prolonged, but is accompanied by much larger variations in the amount and distribution of the rainfall than were experienced in the period of 1876-78. It is, moreover, noteworthy that the cycle or period commenced with excessive rain, continued for a period of three years, and culminating in the year 1893 in an average excess of 9·07 inches, or 22 per cent. of the normal fall. This excess rainfall in India in 1893 was equal to the amount of water necessary to supply its largest canal, the Ganges canal, 300 feet wide, 10 feet deep, for a hundred years. This comparison gives a feeble estimate of the surplus water precipitated over India in 1893, in consequence of the special meteorological conditions and actions of the period.

In order to understand the causes of the partial failure of the crops over at least two-thirds of India in the year 1896, it is necessary to bear in mind the more prominent features of its meteorology, that differ very largely from the meteorological conditions in European countries. The following is a brief statement of the chief features of the two monsoon periods in India.

The year in India may be broadly divided into two seasons or monsoons—viz. the north-east monsoon and the south-west monsoon. These names are derived from the direction of the winds prevailing in the Arabian Sea and Bay of Bengal during the two periods. They are inapplicable over the greater part of India, where the winds are from directions nearly opposite to those indicated by the names of the seasons, and are chiefly determined by the axial directions of the local river valleys. Thus the winds in South Bengal are from south-east, and in Bihar from east, during the south-west monsoon, and are from the opposite directions in the north-east monsoon. It would hence be more appropriate to call the two seasons in India the dry monsoon, and the wet monsoon from their most characteristic features.

The dry monsoon or season usually commences in November or December, and continues until May. Winds of land origin prevail more or less steadily in the interior, and hence the period is usually marked by great dryness of the air and little or no rain. The first three months of this period (December to February), characterised by a comparatively low temperature, are known as the cool weather season; and the second three months (March to May), when the temperature increases rapidly, and culminates in a period of excessive heat in May, as the hot weather season. During the cold weather season, shallow depressions of large extent, the majority of which form in Persia, enter India from Baluchistan and traverse Northern India from west to east, distributing light rain in the Indo-Gangetic plains and heavy snow over the Western Himalayas. The severity of the hot weather season is occasionally relieved by the occurrence of series of thunderstorms and duststorms, which cool the air for brief periods. Over nearly the whole of the interior of India the cold weather and hot weather disturbances occupy a very small portion of the period, and the characteristic features of the dry season are persistent dry weather, with clear skies and large diurnal range of temperature.

The chief crops in Northern and Central India during this period are wheat, barley, linseed, &c., and irrigation either from canals, tanks, or wells is essential in almost all districts for their successful cultivation. If the summer rains cease much earlier than usual, it is not possible to plough and sow the higher

and drier lands, and the area of cultivation in the dry season under these conditions is hence largely diminished. If the winter rains are light and scanty, the crops are more or less severely affected on all the higher lands where irrigation from wells, &c., is necessarily limited.

The rains of the wet season set in suddenly on the west coast of India in the first week of June, and a little later (in the second or third week of June) on the Bengal coast, and extend more or less rapidly into the interior. The prevailing winds of this period are of oceanic origin, and are, in fact, the northward extension of the winds of the south-east trades.

The extension of these winds northwards across the Equator and up the Indian Seas usually beg ns in the third week of May, and gives a complete and permanent change of weather (lasting for five or six months), more especially over the land area of India. The winds due to the extension of these massive humid air currents usually begin to give daily rain to the Malabar coast in the last week of May, and to the Bombay coast on June 4 or 5. The humid currents advance more slowly into the interior, but are usually established before the end of the month over the whole of India. Cloudy, showery, or rainy weather, with a moderately high temperature and small diurnal range of temperature, prevail during the next three months, which are in a striking contrast to the excessively hot and dry weather that has prevailed during the previous two or three months.

The rainfall of India during this period is of the greatest importance, and is sufficient without the aid of irrigation for the crops, except in a few districts (notably Sind and the West Punjab). The rainfall varies considerably in distribution, and slightly in average amount from year to year. The general volume of the current—and hence of the average seasonal rainfall in India—appears to be primarily dependent upon the strength of the currents in the sea areas to the south of India, and hence also of the south-east trades. Consequently it might be expected that any large and persistent variations in the strength of the south-east trades would be reproduced in the strength of the south-west monsoon currents and in the rainfall of the season in India. The local strength of the current in different parts of India varies, to some extent, from year to year, and it has been found that the distribution of the rainfall is largely dependent upon the pressure and other abnormal conditions prevailing in India at the time of its extension, and hence that these can be utilised to forecast the general character of the distribution of the monsoon rainfall. It has been shown, chiefly by Mr. Blanford, that the amount and distribution of the winter snowfall in the Western Himalayas is an important factor in determining these conditions, and hence in modifying the local distribution of the rainfall during the wet or south-west monsoon. Excessive snowfall during the winter proper (*i.e.* December to March), or heavy and unusual snow in April or May, affect the pressure distribution in such a way as to deflect the monsoon currents in their entry into India from one portion of the area (usually North-western India), and determine it more largely than usual to another portion (as, for example, Burma, Bengal or the Peninsula). Under such conditions, one part of the Indian monsoon area receives unusually scanty rain (leading, perhaps, to drought and famine), whilst another area obtains excessive rain. The last notable example of this was in 1891, when Rajputana suffered severely from drought. The winter of 1890–91, in the Western Himalayas, was very severe, and the snowfall excessive and prolonged until May.

It is of the greatest importance to distinguish between the general conditions in the oceanic area (more especially the strength of the south-east trades) affecting the general strength of the monsoon currents prevailing in the Indian monsoon region and the local conditions determining its relative strength in different portions of the Indian land area. For many years —viz. from 1879 to 1891—the local conditions were undoubtedly the predominant factor determining the variation of the south-west monsoon rainfall in India; but the year 1892 introduced conditions and actions, leading to a very large cyclical variation of rainfall, which cannot be explained by local conditions in India, but which appear to be, in part at least, due to variations in the general strength of the south-west monsoon circulation as depending upon corresponding variations in the south-east trades.

The crops during the south-west or wet monsoon may be locally deficient, either from excessive rain and floods or from scanty rains. Partial failure of the crops from excessive rain is usually local in its extension; but the excessive rainfall of the years 1893–94 undoubtedly affected the crops to a serious extent in many parts of the Central Provinces, Central India, and the North-western Provinces, and impoverished the people of these districts to some extent, and hence diminished their capacity to resist the effects of the deficient rainfall and drought in the succeeding years 1895 and 1896.

Deficient rainfall during the wet monsoon is, undoubtedly, the most potent factor in diminishing the staple food crops of India and leading up to food scarcity and famine. The rainfall may be deficient throughout the whole season, as was the case in many districts of the North-western Provinces in the south-west monsoon of 1896; or the rains may cease suddenly and abruptly some weeks earlier than usual, as in the Central Provinces in 1896. In the latter case, prospects may be excellent from the beginning of the monsoon up to the middle or end of September, and then deteriorate rapidly in consequence of the failure of the rainfall necessary for the full growth of the rice and other food crops. This was the case in 1896 over the greater part of the Central Provinces and Bengal, where the partial failure of the rice crop was solely due to the absence of rain in October and November 1896.

The failure of the crops in India, 1896, was more extensive, and spread over a far wider area than has occurred for probably 100 years at least, and its effects were intensified by the four unsatisfactory seasons which preceded it. It was due in a few districts to excessive rain and floods, in a large number of districts to scanty rainfall throughout the whole monsoon, and in others to the early and abrupt termination of the rains from a month to six weeks before the normal date.

The following gives details and data of the more important abnormal features of the south-west monsoon rains of 1896, which were chiefly instrumental in leading up to the very general and partial failure of the summer or wet crops of that year. The table below gives the average or normal date on which the south-west monsoon rains commence in different provinces of India, and the mean date on which they commenced in the same areas in 1896:—

Province	Normal or average date of commencement of south-west monsoon rains	Mean date of beginning of south-west monsoon rains. 1896	Variation from normal date
Bombay (West Coast Districts)	June 5	June 14	9 days later than usual
Central Provinces	,, 10	,, 17	7 ,, ,,
Central India ...	,, 15	,, 21	6 ,, ,,
Rajputana... ...	,, 15	,, 21	6 ,, ,,
Bengal	,, 15	,, 18	3 ,, ,,
Bihar	,, 15	,, 19	4 ,, ,,
North-west Provinces and Oudh	,, 25	,, 21	4 days earlier than usual
East Punjab ...	July 1	,, 25	6 ,, ,,

This table shows clearly that the advent of the monsoon was slightly delayed, more especially in the Arabian Sea and on the west coast of India. The monsoon currents advanced, however, so rapidly into the interior that in Upper India the rains began a few days earlier than usual, establishing that the local conditions in India were favourable. (This was anticipated in the Departmental forecast published in the first week of June antecedent to the arrival of the monsoon, in which it was stated "that the monsoon currents would probably set in on the Bombay coast later than usual, but would advance into the interior more rapidly than usual.")

The monsoon currents held without any general break or interruption throughout the remainder of the month of June, and also during the whole of July and the first three weeks of August, but were less steady than usual. A larger number of cyclonic storms than usual formed in the Bay during this period, as is the rule in a weak monsoon. These storms advanced in the same general direction across a broad belt of country at the head of the Peninsula, stretching from Orissa to Gujarat and Kathiawar. The in-draught to these storms affected the dis-

tribution of the rainfall in two respects: it diminished the rainfall in Bengal and the Gangetic Plain, and distributed it more largely and copiously in cyclonic downpours over the areas traversed by these storms, viz. Orissa, the southern districts of Chota Nagpur, the Central Provinces, Berar, the south-western districts of Central India and Rajputana, Gujarat, and Kathiawar.

The following comparative statement indicates roughly but clearly the distribution of the rainfall during this period from the commencement of the rains to the end of August:—

	Province	Rainfall of period June 1 to August 31			
		Average actual (1896)	Average normal	Variation from normal	Percent. variation
		Inches	Inches	Inches	Percent.
Areas of deficient rainfall	Bengal ...	33·69	44·55	−10·86	−24
	Assam ...	43·91	54·53	−10·62	−19
	Bihar ...	25·67	32·88	−7·21	−22
	North-west Provinces ...	22·42	26·69	−4·27	−16
	Oudh ...	22·47	26·33	−3·86	−15
	Punjab ...	9·99	12·14	−2·15	−18
	Rajputana ...	13·59	16·03	−2·44	−15
	Central India ...	28·82	33·28	−4·46	−13
	Hyderabad, North ...	21·82	22·34	−0·52	−2
	Madras Deccan ...	7·62	10·08	−2·46	−24
Areas of increased or excess rainfall	Orissa ...	45·62	32·85	+12·77	+39
	Chota Nagpur ...	42·16	36·31	+5·85	+16
	Central Provinces ...	51·19	35·69	+15·50	+43
	Berar ...	24·28	24·05	+0·23	+1
	Gujarat ...	45·00	34·00	+11·00	+32
	Kathiawar ...	28·51	20·81	+7·70	+37
	Bombay Deccan ...	31·60	21·34	+10·26	+48
	Madras East Coast North	20·71	18·71	+2·00	+11

The data establish that over the broad belt of country between Orissa and the North Bombay coast, including Orissa, the Central Provinces, the Bombay Deccan, Gujarat, and Kathiawar, the rainfall of the monsoon up to the end of August was in large excess, by amounts averaging from 30 to 50 per cent. It was, on the other hand, in defect by nearly equal percentage amounts over the whole of India to the north of that belt, *i.e.*, in Bengal, Bihar, the North-western Provinces, Central India, Rajputana, and the Punjab. It is assumed in the rainfall maps prepared weekly for the Government of India that a seasonal deficiency in a meteorological district or province of 20 per cent. or upwards is large, and that the crops in such an area will be seriously affected unless the rainfall is very favourably distributed throughout the whole season. The data hence show that the rainfall during the period June to August 1896 in Bengal, Bihar, and the Madras Deccan was in serious deficiency, and that it was also in marked defect in the provinces of Assam, the North-western Provinces, the Punjab, Central India (east), and Rajputana, by amounts verging on what may be termed the danger line. It should, however, be noted that, although the rains over the greater part of Northern India were scanty, they had been on the whole favourably distributed (more especially in Bihar and Bengal), and the chief food crops in these districts only required moderate and seasonable rain during the next six or eight weeks in order to give a fair to satisfactory outturn. The rice crop in Bihar, the eastern districts of the North-western Provinces, the Central Provinces, and Bengal especially, requires fair rain in September to complete its growth. Unfortunately, the rains at this critical period, in September 1896, failed almost entirely in Northern and Central India in consequence of the abnormally early retreat of the humid monsoon currents and the prevalence of dry, clear, and much warmer weather than usual in September and October, at a time when occasional rain is essential.

The monsoon currents withdrew from the whole of Northern and Central India from four to seven weeks earlier than usual, in August and September 1896, as shown in the following table. The conditions and features of the withdrawal and retreat of the current were practically normal in all other respects. The table gives data showing the very early termination of the rains.

Province	Normal or average date of termination of south-west monsoon rains	Mean date of termination of south-west monsoon rains, 1896	Monsoon closed earlier than usual by
East Punjab ...	September 15	August 22	24 days
North-Western Provinces and Oudh ...	„ 30	„ 30	31 „
Bihar	October 15	September 18	27 „
Bengal	„ 31	„ 21	40 „
Rajputana ...	September 20	August 18	33 „
Central India ...	„ 30	„ 28	33 „
Central Provinces	October 15	„ 31	45 „
Bombay ...	„ 15	„ 31	45 „

The preceding data establish that the monsoon rains ceased from three to six weeks earlier than usual, and also that this acceleration was greatest in the rice-growing districts of Bengal, the Central Provinces and Bombay, where it was most prejudicial in its effect on the staple crops.

The general failure of the rains in September and October 1896, is shown most fully by the data of the following table:—

Province	September 1896		October 1896	
	Variation of rainfall of month from the normal	Percentage variation of rainfall of month from the normal	Variation of rainfall of month from the normal	Percentage variation of rainfall of month from the normal
	Inches		Inches	
Assam	−0·23	−2	−3·16	−65
Bengal	+0·85	+8	−3·94	−87
Bihar	−2·38	−28	−2·66	−99
Chota Nagpur	−3·43	−41	−2·92	−100
North-western Provinces	−5·82	−91	−1·47	−99
Oudh	−6·55	−95	−1·59	−99
Punjab	−2·04	−78	−0·22	−65
Berar	−5·85	−94	−2·29	−99
Central Provinces ...	−6·45	−79	−1·98	−100
Central India	−6·12	−93	−1·66	−100
Rajputana	−2·17	−87	−0·26	−89
Gujarat	−6·28	−78	−1·36	−100
Kathiawar	−4·19	−89	−0·69	−100
Bombay Deccan ...	−4·33	−78	−4·19	−84
Madras, Central ...	−2·98	−56	−4·85	−93
„ East Coast North	−1·97	−28	−6·96	−98
Hyderabad, North ...	−5·74	−76	−2·43	−89

The preceding data show clearly the very serious deficiency of rain in September and October. Thus in the month of September, the rainfall over the whole of India north of lat. 12°, with the exception of Assam, Bengal, Bihar, Chota Nagpur and North Madras, was only one-seventh or 14 per cent. of the normal amount, and in the month of October the rainfall over the whole of India north of lat. 14° was less than one-twelfth of the normal, and over the greater part of the area, including Bihar, Chota Nagpur, North-western Provinces, Oudh, Berar, the Central Provinces, Central and North Madras, Gujarat and Kathiawar, the rainfall of the month was practically or absolutely *nil*.

It will thus be seen that in the large area including Bengal, Bihar, the North-western Provinces, Punjab, Rajputana, Central India (east), the wet or south-west, monsoon crops (usually called the kharif) failed to a more or less serious extent: (1) from deficient rainfall throughout the season; (2) from the abnormally early and abrupt termination of the monsoon rainfall three to seven weeks earlier than usual. In another large area including Berar, the Central Provinces, and the greater part of the Deccan and North Madras, although the rainfall during the first three months of the monsoon was more abundant than usual, the early termination of the monsoon, about six weeks earlier than usual, affected the crops almost as seriously as in the first area, including the greater part of Northern and Central India.

The preceding discussion has shown the chief features of the south-west monsoon of 1896, which made it so disastrous a season for the staple food crops in India.

It is natural to inquire whether the deficiency of rainfall in India accompanied a greater determination of the monsoon currents towards, and hence heavier rainfall in, the remaining land areas of the monsoon region.

The chief land areas which obtain, in general, moderate to heavy rains from the south-west monsoon winds (the continuation of the south-east trades of the Indian Seas) are: (1) India; (2) Burma, Siam and the Malay Peninsula; (3) the equatorial lake region of Central and East Africa and the Abyssinian highlands.

In nine years out of ten, when the rainfall is in marked defect in Northern India, it is more or less in excess in Burma; and the monsoon of 1896 was no exception to the rule, as is shown by the following:—

Division	Rainfall from May 31 to October 17, 1896			
	Average actual	Average normal	Variation from normal	Percentage variation
	Inches	Inches	Inches	
Tenasserim	183·86	154·58	+29·28	+19
Lower Burma (Deltaic).	106·59	81·57	+25·02	+31
Arakan	161·74	156·86	+ 4·88	+3

The very limited information I have received indicates that the precipitation was also in excess in Siam.

Information of the rainfall in the third region of summer monsoon rainfall has not yet reached India. I am, however, informed that the curve showing the flood level of the Nile at the gauge stations at Assuan and at the Barrage, near Cairo, at the head of the Delta, for the past year was most unusual. Instead of having one maximum in September, as is usually the case, it presented two well-marked maxima, the first being the ordinary and absolute maximum in September, and the second an abnormal and secondary maximum in November, apparently due to heavy rainfall in October in Abyssinia. Heavy rain is reported to have fallen in the Upper or White Nile Basin in November. The defection of the humid current indicated by this fact is confirmed by the unusual and abnormal easting of the winds in October and November at the Seychelles and Zanzibar. This heavy rainfall hence occurred in the African region at the time when the retreating south-west monsoon was giving unusually scanty rain in Southern India and the Deccan.

It is also probable that the rainfall in the sea area passed over by the monsoon currents in their advance towards India may have been greater than usual. Mr. Blanford, in his monograph on the rainfall of India, has laid down the following principle: "that it is not when the monsoon current is blowing steadily that rain is most probable, but when it is defected from its normal direction by some local irregularity of pressure."

It is not possible at the present time to obtain direct evidence on this point. The rainfall of the Seychelles and Zanzibar during the period June to September of the past five years has, on the whole, varied inversely to that of the same period in India, thus slightly in favour of the assumption that the rainfall in the sea area was somewhat larger than usual during the past two years, and more especially in 1895.

So far as can be judged from the limited data available, it is almost certain that the distribution of the rainfall in the whole monsoon land region has not been compensatory, and hence that the precipitation has, from some unknown conditions or actions, been below the nórmal to a considerable extent, probably more than 5 per cent. of the average of the whole area. It is not possible to infer whether this deficiency has been compensated by a heavier precipitation over the equatorial belt of the Indian Ocean and over the Arabian Sea and Bay of Bengal. The data for the insular stations of Port Blair, Minicoy, Amini Devi and the Seychelles are certainly opposed to this supposition.

It is hence almost certain that the deficient rainfall in India in the past year, 1896, is only a phase of conditions and actions extending over a much larger area.

The variations in the amount and distribution of rainfall in India during the past five years, 1892–6, cannot be explained by the local meteorological conditions, either antecedent to or during the monsoon, and are, in fact, of such a character as to indicate that they are probably mainly due to corresponding variations in the strength of the south-east trades, of which the south-west monsoon circulation is the northward extension from June to October. As the strength of a steady horizontal air movement is directly related to the pressure gradients, the variations of the latter, which are approximately known from the pressure data of the Observatories at Mauritius, Zanzibar, the Seychelles, and Colombo, may be employed to indicate roughly the variations in the strength of the south-east trades from 1892–6.

The following gives the mean differences of pressure between Mauritius and Zanzibar, Seychelles and Colombo (1) for the period June to August, and (2) for the period June to October of each year from 1891 to 1896:—

Year	Mean pressure difference of period June to August		
	Mauritius to		
	Colombo	Zanzibar	Seychelles (observatory opened 1894 April)
	″	″	″
1891	·321	·071	
1892	·339	·087	
1893	·377	·104	
1894	·335	·078	·221
1895	·334	·065	·215
1896	·350	·099	·236
Normal difference...	·335	·080	·230

Year	Mean pressure difference of period June to October		
	Colombo	Zanzibar	Seychelles
	″	″	″
1891	·312	·091	
1892	·324	·102	
1893	·339	·116	
1894	·305	·090	·205
1895	·308	·075	·201
1896	·319	·105	·220
Normal difference...	·310	·095	·210

The preceding data establish conclusively that the mean pressure differences or gradients in the south-east trades region during the south-west monsoon periods of the past five years, 1892–96, exhibit a similar law of variation to that of the rainfall of India. The gradients or pressure differences were above the normal in 1892, 1893, and 1894, reaching their maximum normal in 1893, and considerably below their mean value in 1895. The figures seem to indicate that the maximum and minimum pressure effect precede by some months the maximum and minimum rainfall in India, a very important indication if further experience should show it is a general rule and not a casual coincidence.

The variations of gradient almost certainly indicate corresponding variations in the strength of the south-east trades. That there are variations in the strength of the south-east trades has been suggested by Mr. W. E. Hutchins, Conservator of Forests to the Cape Government, in explanation of the variations of rainfall from year to year in the Cape Colony. In a letter (written in April 1896), which I received from him in June, and sent for publication to several of the Indian newspapers, he says: "The absence of the south-east trades in the Cape throughout the past summer (*i.e.* November 1895 to March or April 1896) has brought abnormal summer rains to the Cape Peninsula, and drought, scarcity and locusts to the bulk of the continent, where the usual summer rains have failed. Are

the south-east trades at present deficient in energy? The south-west monsoon in India is held to be an extension of the south-east trades. After what has happened in South Africa it will be interesting to note the character of the coming monsoon in India. There are two indications pointing to the failure of the coming Indian monsoon (in 1896).

"(1) The failure of the south-east rains in South Africa.

"(2) The cyclical variation of weather in South Africa."

Mr. Hutchins' anticipations were unfortunately fully verified, and confirm the probability of the relation between the varying strength of the south-east trades and the monsoon rainfall of India.

I have recently had my attention called, by Captain Froud, Secretary to the Shipmasters' Society, to the presence in large numbers of icebergs in the Antarctic Ocean, much further north than usual, off the Cape Colony coast, to such an extent, in fact, as to be dangerous to steamers following the "safety track" from London to New Zealand, adopted by several English steamer lines. One vessel met with icebergs as far north as lat. 35° N., and numbers, said to be from 400 to 600 feet above water, have been encountered by steamers during the past eighteen months, at least, in lat. 42° to 45° S., to the south, south-east and south-west of the Cape. The following give extracts from the log of the s.s. *Thermopylæ*:—

1896.	Lat. S.	Long. E.	
September 22 ...	45° ...	49° ...	Passed iceberg ½ mile long and 640 feet high.
,, 23 ...	— ...	— ...	Very large icebergs, with perpendicular sides and flat top, ¾ mile long and 400 feet high.
,, 24 ...	— ...	— ...	Passed two large icebergs and many small pieces.
,, 25 ...	46° ...	70° ...	Several large icebergs seen.
,, 26 ...	46½° ...	75° ...	Last iceberg seen.

formerly, thereby increasing the risk of the southern passage to Australia."

Mr. Allingham, of the English Meteorological Office, has kindly supplied me with a summary, tabulated below, of the data he has collected, indicating the abnormal number and northward extension of icebergs in the south-east of the Indian Ocean during the past two years.

The following summarises the chief features of the remarkable cyclonic variation of rainfall in India during the past five years, and which culminated in partial failure of the crops and scarcity over so wide an area in 1896:—

Year	Rainfall			
	Mean actual	Mean normal	Variation from normal	Percentage variation
1892	46·18	41·09	+ 5·09	+ 12
1893	50·16	41·09	+ 9·07	+ 22
1894	47·56	41·09	+ 6·47	+ 16
1895	38·90	41·09	− 2·19	− 7
1896	36·26	41·09	− 4·83	− 12

If single stations, in the province most largely affected by the abnormal condition of the period, were selected, the contrast between the excess in the years 1892–94 and the deficiency of the years 1895–96 is very marked. The table at the top of p. 115 gives data of total rainfall of period June to October at one station in the Central Provinces, one in the North-western Provinces, and one in Bihar, in illustration of this.

At Allahabad, the headquarters of the Government of the North-western Provinces, the area most seriously affected, the total rainfall in 1894 was practically double the normal, and in 1896 barely half of the normal.

Ship	Date	Position	Number of icebergs seen	Remarks
s.s. *Thermopylæ* ...	June 24, 1895	45° S. 49° E.	12	Some 400 feet high
Armida ...	July 9, 1895	42 S. 43 E.	1	400 feet high
s.s. *Zainui* ...	July 10, 1895, to July 13, 1895	44 S. 45 E. to 45 S. 67 E.	13	100 feet to 200 high
Gainsborough ...	July 15, 1895, to July 17, 1895	42 S. 43 E. to 42 S. 51 E.	5	
s.s. *Port Chalmers* ...	July 27, 1895	45 S. 52 E.		Steamer collided with an iceberg
Queen Mab ...	Aug. 6, 1895	35 30′ S. 20 45′ E.	7	70 feet to 200 feet high
s.s. *Kaikoura* ...	Nov. 17, 1895	45 S. 52 E.	1	Very large
s.s. *Gulf of Lions* ...	Dec. 23, 1895	47 S. 50 E.	1	130 feet high
s.s. *Buteshire* ...	Aug. 5, 1896, to Aug. 7, 1896	45 S. 55 E. to 46 S. 66 E.		Several, mud loose in
s.s. *Thermopylæ* ...	Sept. 22, 1896, to Sept. 25, 1896	45 S. 50 E. to 46 S. 71 E.	30	300 feet to 640 feet high (640 feet by sextant)
s.s. *Tongariro* ...	Oct. 1896	45 S. 50 E. to 47 S. 80 E.	200	Some very large
Loch Fergus ...	Oct. 13, 1896, to Oct. 20, 1896	45 S. 50 E. to 46 S. 78 E.		Numerous icebergs
Firth of Lorn ...	Oct. 27, 1896	43 S. 57 E. to 43 S. 59 E.	3	300 feet high
s.s. *Otarama* ...	Nov. 3, 1896, to Nov. 7, 1896	46 S. 54 E. to 47 S. 77 E.	336	Mud small
s.s. *Stassfurt* ...	Nov. 29, 1896, to Dec. 1, 1896	44 S. 68 E. to 45 S. 79 E.	3	50 feet, 70 feet, 250 high
s.s. *Matatua* ...	Nov. 9, 1896, to Nov. 14, 1896	45 S. 52 E. to 46 S. 81 E.	57	One 420 feet high
s.s. *Pakeha* ...	Dec. 3, 1896, to Dec. 10, 1896	45 S. 50 E. to 45 S. 80 E.		Very many

The captain adds that measurements were carefully taken by the sextant when the icebergs were suitably situated near the track of the vessel.

The captain of the s.s. *Port Melbourn*, in a letter dated London, February 11, 1897, writes: "On our passage out last voyage to Albany (Western Australia), we encountered a number of large icebergs (about forty-five in all) and a quantity of smaller pieces of ice between lat. 44° S. and 45° S. and long. 49° E. and 70° E. The larger icebergs ranged from ¼ mile to 2 miles in length and from 300 feet to 820 feet in height (as measured by the sextant). It is very evident that ice in the Southern Indian Ocean now appears to work its way further north than

The data hence show that there was a strongly marked cyclical variation of the rainfall of India in this period, the maximum of which was 1893, and the minimum (probably) in 1896. In the year of maximum rainfall (1893), the south-west monsoon commenced early and withdrew much later than usual, and gave excessive rain throughout the whole period of its prevalence, whilst that of 1896, the year of minimum rainfall, commenced late, withdrew early, and gave scanty and very deficient rain throughout the whole period. The marked contrast between the two years was, it may be noted, not restricted to the south-west monsoon. In 1893 and 1894 the rainfall was above the normal in each of the four seasons into

Station	Normal rainfall in use previous to 1894	Normal rainfall in use since 1894	1892		1893		1894		1895		1896

which the year is divided in India, whereas from March 1895 to March 1896 it was more or less in defect in each season, as is shown by the data of the following table.

The variations in this table are calculated from the data of over 2000 stations for which normal monthly means have been calculated, and no allowance is made for the area represented by each station. The total annual variation hence varies considerably according to the two methods of calculation, but it will be seen that they agree in the general character of the cyclical variation :—

Year	Rainfall variation of whole of India (excluding Burma)				
	January and February	March to May	June to Sept.	November and December	Of whole year
	Inches	Inches	Inches	Inch	
1892	−0·37	+0·42	+4·39	−0·96	+3·48
1893	+1·42	+3·62	+3·39	+0·49	+8·82
1894	+0·53	−0·10	+7·56	+0·31	+8·30
1895	+0·04	−0·08	−3·27	−0·72	−4·03
1896	−0·45	−1·09	−3·80	+0·33	−5·01

The main features of the rainfall during this period were hence not special to the south-west monsoon, but general and affecting the meteorology of the whole year. This fact indicates that the causes of the periodic variations are not only general, but due to more or less permanent and persistent meteorological conditions or actions affecting the meteorology of the whole period over a considerable portion of the earth's surface.

It has apparently been established in the discussion that the variations of the rainfall in India during the past six years are parallel with and in part, at least, due to variations in the gradients, and the strength of the winds in the south-east trade regions of the Indian Ocean. The discussion has indicated that there are variations from year to year in the strength of the atmospheric circulation obtaining over the large area of Southern Asia and the Indian Ocean, and that these variations are an important and large factor in determining the periodic variations in the rainfall of the whole area dependent on that circulation, and more especially in India. It has also been indicated that these variations which accompany, and are probably the result in part of abnormal temperature (and hence pressure), conditions in the Indian Ocean and Indian monsoon area may be in part due to conditions in the Antarctic Ocean, which also determine the comparative prevalence or absence of icebergs in the northern portions of the Antarctic Ocean.

The economic effects of these very large variations of rainfall during the past five years has been very great, almost disastrous, in India. The variations are so large in amount, and affect so vast an area, as to suggest that meteorological science should have no difficulty in assigning the causes or chain of actions leading up to these effects. Facts have been given in the present paper which suggest an explanation, but it is doubtful whether it can be regarded as satisfactory.

There appear to be only two explanations possible of this periodicity. The first is that it represents large cumulative effects of opposite phases in different parts of the earth. So far as the whole Indian monsoon area is concerned, the variations in different parts have not been compensatory; and the rainfall in 1896 has almost certainly been below the normal, on the mean of the whole area. It would be an interesting study for a Central International Weather Bureau to investigate. So far as can be judged from a brief examination of the weather reports of other countries, there appear to have been no large and marked periodic variation in other parts of the world corresponding to the variation in India—of either the same or opposite phase. It is hence, on the whole, probable that the periodic rainfall variation of the past five years in India has not been compensated by a similar variation of opposite phases elsewhere. If it were the case, it would be purely a question of meteorological investigation.

The second explanation is that this periodic variation of rainfall in the Indian Ocean during the past five years may be one phase of general actions in the earth's atmosphere, due to abnormal variations in the radiation and absorption of solar energy, and hence to some abnormal phase of the sunspot periodicity. Perhaps the observations recorded at Solar Physics Observatories during the past five years may throw light on the question; and if such be the result, it would furnish a powerful argument for India assisting in the work of Solar Observatories to a much larger extent than she has hitherto done.

The question which now affects India most seriously is, whether the rainfall of the present monsoon is likely to be seriously in defect.

An examination of the figures certainly indicates a probability that the mean rainfall of the year will be below the normal. If the causes of the variations were known with certainty, it would probably decide the question. J. E.

THE INSTITUTION OF CIVIL ENGINEERS.

ON Tuesday, Wednesday, and Thursday of last week, May 25, 26, and 27, the Institution of Civil Engineers held a conference. This is a thing unprecedented in the annals of the Institution, it having confined itself hitherto to weekly meetings during the London season. Not only were there daily sittings, many of them proceeding simultaneously, for the reading and discussion of several papers, but there were also excursions to works and "other objects of interest." There was, as well, a conversazione; but this is no novelty for the Institution. A very large number of members attended the meetings, the Westminster Town Hall and the Westminster Guildhall having been retained for the purpose. The general plan of the conference was for one or more members to read a short note by way of initiating a discussion. As there were nearly fifty items in the programme, the congress being divided up into seven sections, it will be evident that in the small space at our disposal we cannot even refer to all the subjects brought forward.

Proceedings commenced at half-past ten on Tuesday, May 25, by the President reading a short address in the Westminster Town Hall, in which the scope of the conference was sketched out. The members then dispersed to the different sections. Section I. was devoted to railways, and the proceedings commenced by Mr. Harold Copperthwaite reading a note on rails and permanent way. He was followed by Mr. F. W. Webb, of Crewe, who read a note on the same subject. The discussion was of an entirely practical and professional nature. Mr. Webb introduced a model of a joint chair; that is to say, a device which combined in itself a rail chair and fishplate. It will be a great boon to railway travellers if this apparatus can be introduced, supposing it will fulfil all the promises made on its behalf by its originator, for there is no doubt that a very great part of the jar and rattle of railway travelling is due to the giving of rails at the joints. This fact was illustrated by means of lead fishplates, which Mr. Webb had used for the purpose of showing what was the amount of deflection at rail connections; it was considerable. The joint chair referred to is of massive construction, and care will have to be taken that too much progress is not made in the direction of rigidity, otherwise there will be repeated the old trouble experienced with stone blocks for sleepers; some flexibility is needful for a good road. In

Section II. there were also two subjects introduced, the first relating to concrete in marine works, and the second in relation to approaches of docks. Sections III. and VII. sat conjointly, the former of these two dealing with machinery, and the second with applications of electricity. Messrs. Preece, Ellington and Dr. Hopkinson contributed the notes which opened the discussion; the combined subject for the day being the transmission of power by electricity, by water, and by other agents. Mr. Ellington naturally claimed that water was superior to electricity, a statement which was equally naturally disputed by the electricians present. It is needless to say nothing definite was settled on this many-sided question. Perhaps the most interesting contribution to the discussion was that supplied by Prof. Forbes, who had come to the conclusion that the distance over which power might be profitably transmitted by electricity was not far short of 1000 miles. He had been consulted as to the transmission of power from the Victoria Falls on the Zambesi to the gold mines in Matabeleland and the Transvaal. At first he considered the suggestion altogether impracticable; but on putting together figures with a view to prove its absurdity, some ideas had occurred to him which led him to believe that the scheme was not so chimerical after all. The electrical world will look forward with interest to the development of Prof. Forbes' plans.

The proceedings in Section IV., which deal with mining and metallurgy, were of a very practical nature. The most interesting of the contributions was that by Mr. Bennett H. Brough, in which he gave some interesting particulars of deep mines in the United Kingdom. At Pendleton Colliery, near Manchester, the workings were 3474 feet below the surface, that being the deepest working in Great Britain. The deepest metal mine in the United Kingdom is the Dolcoath Tin Mine in Cornwall, which is 2582 feet deep. These figures are, of course, exceeded in mines abroad; a shaft in the copper mines of the Lake Superior district, the deepest in the world, going down to 4900 feet.

Section V. was devoted to shipbuilding. The proceedings were opened by a very instructive note by Mr. Archibald Denny, of Dumbarton, in which he dealt with the practical application of model experiments in merchant ship design. As is well known, Mr. Denny's firm have the only experimental tank of a private nature in the world, it being modelled after the design of the late Mr. Froude. Mr. Denny gave a description of the method of procedure in carrying out these model experiments. A very good discussion followed the reading of this paper, in which Mr. R. E. Froude, Sir Edward Reed, Mr. Thornycroft, Prof. Biles, Sir William White, and others took part. Section VI. was devoted to waterworks, sewerage, and gas works. On the first day of the meeting the proceedings were devoted to a consideration of the law of allocation of underground water.

On the second day of the conference, Wednesday, May 26, in Section I. (the railway section), the discussions turned chiefly on the economics of light railways. In Section III. the most interesting paper was that contributed by Mr. Bryan Donkin, on "Important Questions in the Economic Working of Steam Engines and Boilers." The author pointed out that for greater efficiency it was desirable to adopt high pressures up to 250 pounds, efficient steam-jacketing, reduction of clearance volumes in surfaces of cylinders, and a high number of revolutions. He pointed out that moderately superheated steam had long been employed on the continent, but was coming into favour here very slowly. Superheating reduces cylinder condensation, but, of course, is attended by practical difficulties, and requires more highly-skilled attendance. Mr. Donkin also impressed on the meeting the advantage of using entropy diagrams. He stated that multi-cylinder engines, with twenty or thirty expansions, are very economical, but are only admissible where the barrels and covers are thoroughly steam-jacketed, or superheated steam is used. He also advised greater compression than is generally used. He advocated the statement of economy in terms of thermal units per I.H.P. hour, and also in thermal units per break H.P. hour, whether for saturated or superheated steam. In dealing with steam boilers he pointed out the need of analyses of gases to determine the percentage of CO_2, CO, and O. He rightly stated that no boiler experiments are complete without such gas analyses. Reference was also made to the use of coal finely ground, which, it is said, was being used on the continent. The information is interesting, remembering the great efforts made many years ago to use powdered coal, and the difficulties which led to the failure of the scheme. It would be interesting to know how these difficulties had been overcome. This note concluded by an advice that all engine and boiler trials should be tabulated in uniform manner. It is satisfactory to know that the subject is likely to be taken up by the Institution. A speech which the President, Mr. Wolfe Barry, made, gives hope that a Committee will be formed to consider and report on this matter, and it is probable some legislation by the Institution will follow. In order, however, to make the Committee complete it should take a wider range than the Institution of Civil Engineers, which, although our premier engineering society, is not the only representative engineering body, more especially in regard to mechanical engineering. Petroleum as a steam-engine fuel was the subject introduced by Mr. Aspinall, the Locomotive Superintendent of the Lancashire and Yorkshire Railway. An interesting discussion followed the reading of this note, but it took rather a practical than a scientific turn. There is no doubt that liquid fuel can be used with great convenience on locomotives, and would speedily supplant coal if it could be obtained in sufficiently large quantities and at a sufficiently low price. At present it is only now and then that it can be economically used; still the Great Eastern Railway have a number of liquid-fuel-burning locomotives in fairly constant use on their system.

The Electrical Section on this day discussed two subjects—namely, "Should generating plant be mounted on springs?" and "Turbines as applied to dynamos." In regard to the former, it may perhaps be said that the gist of the discussion pointed to the fact that when generating plant has been mounted on springs, the results have not been altogether satisfactory; but, nevertheless, by mechanical improvements and alterations in detail, the system might be sufficiently perfected to enable it to be worked advantageously. The problem of using turbines was introduced by the Hon. C. A. Parsons. The subject is an interesting one, and the author was well able to deal with it had he been allowed further time. As it was, the note was decidedly meagre, and the discussion disappointing. Perhaps the paper of most interest on this day was that read in the Shipbuilding Section, by Mr. Parsons, in which he gave some particulars of the wonderful steam-turbine-driven boat which he has recently designed and built. The *Turbinia*, the boat in question, is 100 feet in length, 9 feet wide, and 3 feet draught amidships, having a displacement of 44½ tons; she is, therefore, only half the length, and of very greatly less displacement, than the torpedo-boat destroyers, which have been, hitherto, our fastest vessels. With this little boat, however, Mr. Parsons has made a speed of 32¾ knots; but he anticipates that when some alterations have been made in the machinery, still higher speeds will be reached: we believe up to 34 knots. There is a water-tube boiler and three steam-turbines working on the compound system in series. Each of these turbines has its own propeller shaft, and on each shaft there are three screws threaded in line. The most remarkable part of the machinery is that the propellers make 2200 revolutions per minute, in order that they may be worked direct from the steam-turbines, which must necessarily revolve at a high speed. The I.H.P. is 2100, and the consumption of feed water per I.H.P. per hour, 14½ lbs. The weight of the main engines is 3 tons 13 cwt., and the total weight of machinery, including water in boiler, &c., 22 tons. Thus nearly 100 H.P. is developed per ton of machinery, and nearly 50 H.P. per ton of displacement of boat; it need hardly be said that the figures are unprecedented.

On the last day of the meeting a large number of papers were read; to these we can only make brief reference. In a discussion on ball and roller bearings, Prof. Goodman gave some interesting details of experiments he had made with a bearing having an 8-inch diameter ball-race of the thrust-block type, which ran at 1600 revolutions. He had tried the system of using four points of contact between the ball and race, which had been advocated by a correspondent to a technical journal, and which was said to give the perfect rolling contact, but had found that the system would not work satisfactorily; and it was only when he fell back on the more ordinary double-contact system, that he met with success. A paper by Prof. Biles, in the Shipbuilding Section, on "Improved Materials of Construction," led to an interesting discussion, in the course of which a good deal was said about nickel steel, which is certainly the coming material for shipbuilding if the question of price can be satisfactorily settled; to effect which further deposits of nickel must be discovered and worked economically. In the Harbour and Docks Section, the Hon. R. C. Parsons described an automatic dredg-

ing machine he had devised. There was a good discussion on the decimal system, initiated by a note by Captain Sankey; and to the same section, Mr. Spagnoletti contributed a note on the equilibrium system of feeding electric railways. There were two good papers in the Railway Section: one on "Standardising of working loads and working stresses for railway bridges," and the other on "The use of small scale experiments in some engineering problems." These were contributed by Mr. Moncrieff and Mr. Mallock respectively.

THE POPULATION OF RUSSIA.

THE results of the first one-day census, which was made throughout the width and breadth of the Russian Empire on February 9 last, were expected with great interest. The last census was made in 1851, and a partial one in 1858; and yet it was not a census proper, for the local police authorities on the spot merely made lists of the permanent residents and taxpayers in each locality. After much preparatory work, it was decided to make, this year, a "one-day census"; that is, in the lists which had to be made for each house in each locality, all those persons who spent the night in a given house and in a given locality on February 9 (or about that date in the villages), had to be mentioned, whether they were permanent residents or not. It was quite a novel experiment, which was looked at with little confidence; but the Vice-President of the Russian Geographical Society, who had had already a great deal of experience with such censuses as they were made, since 1870, in separate big towns (in these censuses the illiterate population filled their lists, as a rule, admirably well), insisted upon the new method being accepted. The census was organised under his guidance, and seems, so far as can be judged, to have been quite successful. The items, obtained from all the local committees, partly by telegraph—with the exception of some parts of the province of Yakutsk—are now published; and the population of the empire appears from them as follows:—European Russia, 94,188,750; Kingdom of Poland, 9,442,590; Grand Duchy of Finland (Finnish yearly census), 2,527,801; Caucasia, 9,723,553; Siberia and Sakhalin, 5,731,732; the Kirghiz Steppes, 3,415,174; Turkestan, with the Trancaspian Region and the Pamirs, 4,175,101; Russian subjects in Bukhara and Khiva, 6412; total, 129,211,113. The corresponding figures, in 1851, were: European Russia, 52,797,685; Poland, 4,852,055; Finland, 1,636,915; Caucasia, 4,436,152; Siberia, 2,437,184; Steppes, 1,220,654; total, 67,380,645. It may thus be said that although the percentage of births is very high in Russia, it took nearly fifty years for the population to double.

An English writer about Russia made, some time ago, the remark that Russia suffers from *a polism*, that is, from a want of towns. This want has lately very much disappeared. There are now in the empire no less than 19 towns having a population of more than 100,000 (out of which two in Poland, two in Caucasia, and one, Tashkend, in Turkestan); 35 towns with populations from 50,000 to 100,000; and 69 towns with populations of from 25,000 to 50,000. St. Petersburg has already attained the figure of 1,267,023, and Moscow approaches the million (988,610).

It is worth mentioning that no less than 230,000 persons took part in the census; very many of them were volunteers, who were recruited among the students of the Universities and the High Schools.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Prof. H. A. Miers, F.R.S., and Mr. W. Garstang, have been appointed examiners for the Burdett-Coutts Scholarship.

An examination for one or more Natural Science Demyships and Exhibitions will be held at Magdalen College in October. The value of the Demyships is £80 per annum. Candidates must be under nineteen years of age on the day of election, October 18.

The Right Hon. John Morley delivered the Romanes Lecture in the Sheldonian Theatre on Wednesday last. The subject was Machiavelli.

CAMBRIDGE.—Dr. Alex. Hill, Master of Downing College, and University Lecturer in Anatomy, has been elected Vice-Chancellor for the ensuing academical year.

Dr. R. D. Roberts has been appointed a Governor and Member of Council of the University College of Wales, Aberystwyth.

The first Smith's Prize has been awarded to Mr. E. T. Whittaker (bracketed second wrangler 1895), of Trinity College, for his essay on "Multiform Functions." The second prize is divided between Mr. R. C. Maclaurin (twelfth wrangler 1895), of St. John's College, for his essay on "Solutions of the Equation $(\nabla^2 + \kappa^2)\Psi = 0$ in Elliptic Co-ordinates," and Mr. A. E. Western (seventh wrangler 1895), of Trinity College, for his essay on "Quadratic Complex Numbers." The essays of Mr. C. Godfrey, of Trinity, Mr. T. J. I. Bromwich, of St. John's, and Mr. B. Hopkinson, of Trinity, receive honourable mention.

Mr. A. Sedgwick, F.R.S., has been reappointed a Manager of the Balfour Fund for five years. The University table in the Marine Biological Laboratory at Plymouth is to be occupied by Mr. S. D. Scott, of King's; the corresponding tables at Naples are assigned to Mr. F. B. Stead, of King's, and Mr. K. R. Menon, of Christ's.

Prof. Lewis announces a course of lectures and demonstrations in Crystallography during the long vacation. Dr. Kanthack, Deputy Professor of Pathology, will give courses in Bacteriology, in Morbid Anatomy and Histology, and in Pathology.

The Examiners for the Mathematical Tripos announce that ninety men and twenty women "have acquitted themselves so as to deserve honours."

Honorary degrees will, on June 17, be conferred on the Archbishop of Canterbury, Lord Lansdowne, the Chief Justices of England and South Australia, a number of the colonial premiers—Sir George Goldie, Sir Arthur Arnold, Sir John Kirk, F.R.S., and Sir William H. White, F.R.S.

Dr. Percy Gardner, Lincoln Professor of Archæology at Oxford, Dr. Sydney H. Vines, F.R.S., Sherardian Professor of Botany at Oxford, and Dr. H. Marshall Ward, F.R.S., Professor of Botany at Cambridge, all of whom were formerly Fellows of Christ's, have been elected Honorary Fellows of the College.

THE following are among recent appointments:—Dr. J. L. Prevost to be full Professor of Physiology at Geneva; Dr. E. Kaufmann, Privat-docent in Anatomy at Breslau, to be Professor; Dr. K. Zeisig, Assistant Professor of Physics in the Darmstadt Technical High School, to be full Professor; Dr. Max Wolters, Privat-docent in Anatomy at Bonn, to be Professor; Dr. Ludwig Heim to be Assistant Professor of Hygiene and Bacteriology at Erlangen; Dr. M. Siegfried to be Assistant Professor of Physiological Chemistry at Leipzig; Prof. A. J. Moses to be Professor of Mineralogy, and Mr. H. M. Howe Professor of Metallurgy, in Columbia University; Mr. W. G. McMillan, Lecturer in Chemistry and Metallurgy at Mason College, Birmingham, to be Assistant Secretary of the Institution of Electrical Engineers.

THE name of the Michigan Mining School has just been legally changed to the Michigan College of Mines. It is proposed to make the tuition fees approximately the same as those charged by other advanced technical schools in America. When the school was working out its policy, it was thought wisest not to charge tuition, but to collect as wide a constituency as possible in order that there might be all possible chance to make the methods as broad and thorough as could be done. It was also deemed hardly just to the students to demand tuition until the institution was much better equipped for its work than the public assistance given during the first decade of its existence permitted. Now that success has been attained in educating men for practical work, the institution seems fully warranted in charging hereafter for its instruction. The new regulation comes into effect immediately after August 19.

A ROYAL charter, dated May 11, has, says the *Educational Times*, been granted for the establishment in Sheffield of a University College. The council of Firth College, the executive committee of the Sheffield Technical School, and the council of the Sheffield School of Medicine petitioned that those institutions should be consolidated and included in one college, having for its object the provision of such an education as might enable residents in the city and neighbourhood to qualify for degrees at any of the Universities in the United Kingdom. It was represented that the endowments of the institutions were of the aggregate value of 100,000*l*., and that there was reason to anticipate further contributions to a large amount after the incorporation of the College. The charter now granted sets forth, amongst other things, that the institution shall be known as

"The University College of Sheffield," and that women may participate in the benefits, emoluments, and government of the College to such an extent and in such a manner as the statutes of the College shall prescribe. There is to be no religious test for students, teachers, or other officers. The first president is the Duke of Norfolk, who is to hold office for five years, and be eligible for re-election. The first vice-presidents are Sir F. T. Mappin, Sir Henry Stephenson, Dr. H. C. Sorby, and Dr. Dyson.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 13.—"On a New Method of Determining the Vapour Pressures of Solutions." By E. B. H. Wade, B.A., Scholar and Coutts Trotter Student of Trinity College, Cambridge. Received April 26.

The statical methods, which have hitherto alone been capable of furnishing results between 60° C. and 100° C., have been attended with serious errors. The apparatus employed in this research was in conception similar to that of Sakurai, except that it was in duplicate, a divided steam supply passing through two U-tubes placed in parallel. It differed, however, from his apparatus in several important particulars, which cannot be adequately described in a brief notice.

Suffice it to say, that the pressure on the contents of the two U-tubes being the *same*, could be adjusted to any convenient value, and that the method of thermometry being the differential platinum one, the *difference* only of the boiling-points of pure water and salt solution, in their respective U-tubes, was recorded. Two series of observations were made at a pressure of 760 mm., in one of which a small external heat supply was used to compensate the condensation in the U-tubes, and a second in which it was found possible to dispense with it.

Neither method gives results differing systematically from the other, though the latter method was greatly preferred.

The substances examined were the chlorides of lithium, calcium, strontium, sodium, and potassium, and bromides of the two last named. A full discussion is here impossible, but we may notice that in all cases the ratio increase of boiling-point to concentration is of the same order as that calculated from Arrhenius' theory, but that the discrepancy always exceeds the experimental error, except in the case of potassium chloride, and is particularly great in the case of calcium chloride. The latter substance gave less well-defined boiling-points than the others which were investigated, for some reason as yet unknown, and the experimental error was here certainly at its greatest, but still not nearly enough to account for the difference.

May 14.—"An Attempt to cause Helium or Argon to pass through Red-hot Palladium, Platinum, or Iron." By William Ramsay, F.R.S., and Morris W. Travers. Received April 9.

A tube of hard, infusible glass was connected at one end with the reservoir of the gas under experiment, helium or argon. Into its other end was corked a tube of platinum, closed with a palladium cap, or, if iron was the metal under experiment, with a tube of thin wrought iron, also closed at the end; the closed end of the interior tube was placed so that it could be raised to a bright red heat by bringing a blow-pipe flame to bear on the hard glass tube. The open end of the metal tube was cemented to a glass tube, attached to a Töpler's pump, and provided with a Plücker's vacuum tube, so that the spectrum of any gas passing through the metal could be observed. This afforded, at the same time, a most delicate test of the presence of the gas under experiment. The metal tube was exhausted, until green phosphorescence appeared in the vacuum tube, and the gas, helium or argon, was admitted into the space between the glass and the metal tube, at atmospheric pressure. The glass tube was then heated to the highest temperature attainable with a blow-pipe—perhaps 900° or 950° C. In no case, whether the metal tube consisted of palladium, platinum, or iron, was there the smallest transpiration of gas, even after half an hour. The phosphorescent vacuum remained in all experiments quite unimpaired.

Physical Society, May 28.—Mr. Shelford Bidwell, President, in the chair.—Mr. Elder read a paper, communicated by Dr. Albert A. Gray, on the perception of the difference of phase by the two ears. The investigation relates to certain acoustical results obtained some years ago by Dr. S. P. Thompson; they may be summarised as follows: (*a*) When two simple tones in opposite phases are conveyed separately, through tubes or otherwise, to the two ears, the sensation of sound appears localised at the back of the head. (*b*) If the respective tones from two forks mistuned to give "beats" are conducted separately to the two ears, they still produce the sensation of "beats"; and, to the observer, this sensation also seems localised at the back of the head. The "beats" are distinct, but there are no true silences, at any rate so long as attention is fixed on the note. (*c*) Although "beats" are heard under these circumstances, no beat-tones are discernible by the binaural method. The author proceeds to explain the phenomena on the assumption that there is a physiological connection between the nerves of both ears. His evidence is derived from the following experiments: (*d*) A vibrating fork is held opposite one ear; the opposite ear is then closed by a finger; the sound of the fork now appears louder to the open ear. (*e*) If the fork is held opposite one ear, and the chain of ossicles of the second ear is then pressed gently inwards by a fine probe, the sound of the fork is heard with increased loudness by the first ear. (*f*) If the chain of ossicles in the second ear is dragged outwards by rarefaction of the air in the meatus, the above changes in loudness are no longer perceptible. The theory put forward by the author in explanation of these results is that they are due to reflex contractions of the tensor tympani or stapius (or more probably both) of the first ear. A further observation, of Pollak, is also brought to bear upon the question, *i.e.* (*g*) stimulation of one cochlea by sound causes contraction of the tensor tympani of both ears, and the contraction is permanent while the sound continues. This is known to be true for the lower animals, and is probably true for man. With regard to (*a*), the author observes that the muscular sense is there being appealed to in a manner quite new to it. The tympani are by nature trained each to relax or expand with the other, and they are thrown out of reckoning if the phases differ. Or, again, the stimuli from the two ears may collide at one of the lower nerve centres, and thus be annulled before any intimation has been received by the brain. The path taken by such stimuli is from the nucleus of one nerve, just after its entrance into the medulla, across to the corresponding nucleus of the opposite side. In these nuclei the stimuli from both ears mix. Some of the nerve-fibres have no nuclear intercommunication at the base of the brain; consequently, stimuli passing by these paths are not subject to interference. This agrees with (*b*), where the silences are not complete. (*h*) It is to be observed that beat-tones are sometimes perceived by the ear under circumstances where they cannot set a resonator into vibration. This indicates that beat-tones may be produced either in the ear or nerve-centres of the listener, and not exteriorly. (*i*) It has been shown by Dr. Thompson that when two simple tones, such as in ordinary hearing produce a differential tone, are led singly to the ears, no differential tone is heard. From this the author concludes that differential tones are not produced in the mind of the listener, nor in any of the cerebral centres. From (*h*) and (*i*) together, the point of production is restricted down to the ear itself; something of the sort was suggested by Helmholtz. Again, from (*g*), it appears that when two notes are sounded so as to give a differential tone, the tensor tympani must be in a state of continual contraction, for the intervals of silence are too short to permit of any relaxation. Meanwhile, there are certain periods during which the tympani membranes are not acted upon by any force external to the ear. The author is of opinion that if the movements of the ossicles upon one another were absolutely frictionless the membranes would come to rest in a position where the force of the contracting muscle was balanced simply by the tension of the membrane and the ligaments of the ossicles; but since the articulations of the ossicles have some friction, the equilibrium is otherwise, and he conjectures that the state of affairs is such that any force acting upon the hammer, tending to draw it inwards, produces a slight jerk, and this repeated gives the necessary impulses for the sensation of differential tones. The mechanics of this theory is not fully worked out.—Mr. J. Rose-Innes read a paper on the isothermals of isopentane. The author takes advantage of the recent experimental work of Ramsay and Young, upon the thermal properties of isopentane, to test a formula giving the relation of pressure to temperature for gases generally, over a considerable range of volume. From the linear equation, $p = bT - a$, for the pressure at constant volume, where a and b are functions of the volume, no formula could be found to give close agreement with observed results. More definite results are obtained by examining a quantity depending upon a and b together;

such a quantity is the temperature τ, at which, for each volume, the substance behaves as a perfect gas. It is shown by tables that τ is nearly a constant for volumes from 350 to about 8. Below volume 8 it diminishes very rapidly with volume. A further investigation refers to the $[(av^2)^{-1}; v^{-\frac{1}{3}}]$ curves of Young, for isopentane, and a corresponding formula. At volume 3·4 on this curve there is a decided peak, suggesting discontinuity. Ether gives a similar curve, and the question arises whether such curves would not be better represented by two or more equations. Prof. Young said the diagrams representing the observed and calculated isothermals were probably the best ever obtained. Divergence among the values of τ was explained in part by the smallness of the angle between the theoretical isochor for a perfect gas, and the real isochor. The point of coincidence was difficult to define. Moreover, the values of τ were obtained from "unsmoothed" values of v. The evidence against the linear law consisted in a certain similarity in the shape of the different curves. It was not easy to see where experimental errors could come in. The peak was a very striking feature of the curves, and the agreement between the results with ether and those of isopentane was very remarkable. These two substances had their boiling-points close together, their critical temperatures close together, and their molecular weights nearly alike. The two substances not only agreed in each giving a peaked curve, but the peak corresponded to almost identical volumes. Prof. Young hoped at some future time to examine normal pentane, and to determine whether τ was a constant for this substance also.—The President proposed a vote of thanks to the authors of the papers, and the meeting was adjourned until June 11.

CAMBRIDGE.

Philosophical Society, April 26.—Mr. F. Darwin, President, in the chair.—On the apparent electrification in an electric field at the bounding surface of two dielectrics, by Prof. A. Anderson.—On luminosity attending the compression of certain rarefied gases, by Mr. H. F. Newall. This paper contains a description of the circumstances under which phosphorescence has been observed by the author when certain rarefied gases (initially at a pressure of about 0·01 mm. to 0·05 mm.) are compressed into a volume about one-twentieth of the initial volume. The explanation of the phosphorescence in the case when oxygen is the gas used appears to be in agreement with the explanation given by Sutherland (*Phil. Mag.*, March 1897), of anomalies observed by Bohr and Crookes in the compression and rarefaction of this gas. According to Sutherland, in the rarefaction of oxygen a point is reached (pressure 0·7 mm.) when oxygen begins to be converted into ozone, and below the pressure 0·15 mm. the gas is entirely ozone. Between the pressures 15 mm. and 0·7 mm. the gas obeys Boyle's law as oxygen, and below 0·15 mm. it obeys Boyle's law as ozone. Between the pressures 0·7 mm. and 0·15 mm. the gas is a mixture of oxygen and ozone. Sutherland is led to the view that in the compression of ozone from the lowest pressures, the ozone begins, when the pressure reaches the value 0·15 mm., to be knocked to pieces in virtue of the frequency of collision between ozone molecules being the same as that of some natural vibration in the molecule. It appears that in the phosphorescence observed by the author as arising during compression of the rarefied gas from a pressure of about 0·02 mm. to pressures lying between 0·3 mm. and 0·5 mm., the ozone is converted into oxygen, and the energy evolved is regarded as resulting in phosphorescence. It is not clear, however, what part is played in the phenomena by the impurities, but it seems certain that their presence is of importance, if not essential for the production of the phosphorescence. The spectrum emitted by the phosphorescent gas is very striking, and consists of four bright bands, coinciding with those which Schuster has described as belonging to the spectrum of the negative glow of oxygen. When the same mixture of gas is at a highe ıpressure, it is possible to produce in it a bright phosphorescence by passing a momentary electrical discharge through it by Prof. J. J. Thomson's method. The phosphorescence is faint at a pressure of 0·6 mm., is at a maximum about 0·4 mm., and is not visible at a pressure below 0·1 mm. (These pressures vary with the impurities present in the mixture.) In the electrical production of phosphorescence in oxygen, it would appear (1) that the gas was initially mainly oxygen, (2) that the momentary discharge supplied it quickly with energy and converted it into ozone, and (3) that the ozone slowly reverted again to oxygen with phosphorescence. In this case, however, the spectrum exhibits no bright lines or bands, but is simply continuous. The author offers no explanation of the difference in the spectra in the two cases of phosphorescence, but calls attention to the probable importance of the observation in connection with astronomical matters and, in particular, with the luminosity of extended nebulæ.

PARIS.

Academy of Sciences, May 24.—M. A. Chatin in the chair.—Tools and weapons of the Copper Age in Egypt: methods and manufacture. New researches, by M. Berthelot. The objects described belong to most ancient Egyptian times, and consist of practically pure copper, no tin being present in any case. A careful examination of some copper needles, found in a tomb at Abydos by M. Amelineau, showed that they had been prepared from a thin lamina of metal, by folding over and subsequent forging. A small chisel obtained from the same place was found to have been made in a very similar manner. A hollow needle was formed from thin copper leaf, in a manner very similar to that employed at the present time in the manufacture of helical tubing for bicycles.—On some liquids contained in antique vases, by M. Berthelot. A liquid found in a flask near Rheims, probably dating from Roman times, showed that the flask originally contained a fat, into which, the flask being open, water filtered in.—Action on light upon gas mixtures, in case where it causes combination, especially on mixtures of hydrogen and chlorine, by MM. Armand Gautier and H. Hélier. No hydrochloric acid is produced from a mixture in equal volumes of hydrogen and chlorine if the latter are prepared and kept in the dark. This is the case even after prolonged exposure, one experiment extending over fifteen months. Similar results were obtained if the mixture was submitted to a very feeble illumination, such as a candle.—New study of tempests and tornadoes, by M. H. Faye. Remarks by the author on the presentation of his work to the Academy.—On the stay of General Poncelet at Saratow, by M. Germain Bapst.—New improvement of the grisometer, by M. N. Gréhant. The instrument is placed in a jacket with parallel glass sides, through which water is kept running.—The surface of cast-iron, kept at a red heat, is able to transform carbonic acid into carbon monoxide, by M. N. Gréhant.—On the elastic vibration and resistance of cannon, by MM. F. Gossot and R. Liouville.—Scientific mixtures, by M. Constant Dubois.—Remarks by M. Mascart on a catalogue of meteorological observations made in France since 1850, taken from the *Annales du Bureau central météorologique.*—On some doubts cast upon the laws of Colonel Goulier relating to the variations of length of levelling sights, by M. Ch. Lallemand. The observations cited, which are mostly produced graphically as curves, all go to confirm the accuracy of the conclusions drawn by Goulier.—On the reflection of light by a long and narrow surface, by M. Gouy. Some remarks on a paper by MM. Nichols and Rubens.—On a phosphorescent anti-anodic system, and the anode rays, by M. C. Maltézos.—On the properties of certain parts of the spectrum, by M. Gustave Le Bon. A reply to the criticisms of M. Becquerel concerning the transparency of ebonite for rays of low refrangibility.—On the precipitation of zinc sulphide in the estimation of this metal, by M. J. Meunier. The difficulties observed in the precipitation of zinc as sulphide are caused by the presence of a large excess of ammonium sulphide; they disappear if only just sufficient hydrogen sulphide is present to cause the complete precipitation of the zinc.—Remarks relating to the heat of formation of the sodium derivatives of acetylene, by M. de Forcrand. Taking into account the latent heat of fusion of acetylene, the latter being deduced from observations by Villard on the heat of formation of the hydrate $C_2H_2 + 6H_2O$, the amounts of heat developed by the successive replacements of the two hydrogen atoms in acetylene by sodium are very nearly equal, the formation of C_2HNa giving out a slightly greater amount (2 Cal.) than that of C_2Na_2.—Some new combinations of pyridine, quinoline, and piperidine with metallic salts, by M. Raoul Varet. — On the preparation of furfurane, by M. P. Freundler. The dry distillation of barium pyromucate gives a poor yield of furfurane, owing to the formation of gaseous products in a secondary reaction; but a quantitative yield is obtained on heating pyromucic acid in small quantities in sealed tubes at 260° to 275°, five grams of the acid giving in this way more furfurane than is obtained by the dry

distillation of one hundred grams of the barium salt.—Solubility of ecgonine, by M. Œchsner de Coninck. The solubility of ecgonine is given for twenty-five organic solvents.—Comparative study of the changes in the respiratory quotients of fruits during ripening, by M. C. Gerber.—On the denaturation of alcohol, by M. Ernest Barillot. It is shown that the method of Dr. Lang employed in Switzerland for the denaturation of alcohol is of little use, since a simple treatment with a bisulphite, followed by a fractional distillation, is sufficient to recover 70 per cent. of the alcohol in a pure state.—On the embryonic shell of the Lamellibranchs, by M. Félix Bernard.—Disease of the branches of the mulberry in Turkey, by MM. Prillieux and Delacroix. The disease is caused by the attack of a parasite, *Sclerotinia libertiana*.—The subterranean hydrography of the Devoluy, by M. E. A. Martel.—Trophic troubles following the section of the posterior medullary roots, by M. J. P. Morat.—Influence of the stretching weight upon the heat disengaged by muscle during contraction, by Mlle. M. Pompilian.—On the antiquity of tatooing as a mode of treatment, by M. Fouquet.—Medico-legal appreciation of traumatic lesions and determination of individual identity by the X-rays, by M. Foveau de Courmelles.—On the three French balloon ascents and the third international experiment, by MM. Hermite and Besançon.—On the formation of acetic acid in a gas battery, by M. Gaudet.—On a means of stopping a leak from the outside of a ship, by M. Burgal.

DIARY OF SOCIETIES.

THURSDAY, June 3.

Royal Society, at 4.—Election of Fellows.—At 4.30.—The Sensitiveness of the Retina to Light and Colour: Captain Abney, F.R.S.—On the Mechanism by which the First Sound of the Heart is produced: Sir R. Quain, F.R.S.—Mathematical Contributions to the Theory of Evolution. On the Relative Variation and Correlation in Civilised and Uncivilised Races: Miss Alice Lee and Prof. K. Pearson, F.R.S.—An Investigation on the Variability of the Human Skeleton, with especial reference to the Naquada Race, discovered by Prof. Flinders Petrie in his Explorations in Egypt: E. Warren.—On the Brains of Two Sub-Fossil Malagasy Lemuroids: C. I. Forsyth Major.—(1) On the Dielectric Constants of certain Frozen Electrolytes, at and above the Temperature of Liquid Air; (2) On the Dielectric Constants of Pure Ice, Glycerine, Nitrobenzol, and Ethylene Dibromide, at and above the Temperature of Liquid Air: Prof. Fleming, F.R.S., and Prof. Dewar, F.R.S.—Preliminary Communication on the Nature of the Contagium of Rinderpest: A. Edington.

Linnean Society, at 8.—Observations on Termites: Dr. G. D. Haviland.—On the Genus Ramulina: Prof. T. Rupert Jones, F.R.S., and F. Chapman.

Chemical Society, at 8.—On the Thermo-chemistry of Carbohydrate Hydrolysis; On the Thermal Phenomena attending the Change in Rotatory Power of Freshly-prepared Solution of certain Carbohydrates, with some Remarks on the Cause of Multirotation: Horace J. PLANT PATHOLOGY.

Diseases of Plants induced by Cryptogamic Parasites. By Dr. Karl Freiherr von Tubeuf. English Edition, by William G. Smith, B.Sc., Ph.D. Pp. xv + 598. (London: Longmans, 1897.)

WHEN the German edition of this work appeared, early in 1894, it at once took rank as one of the most comprehensive and accurate treatises on the subject that had as yet appeared, and the English edition we now have to welcome still deserves this tribute to its merits, for the author has taken the opportunity of adding considerably to the already bulky volume.

The fungus-diseases of plants now number so many forms, that no apology is necessary for treating them separately from the very numerous other diseases of plants; but it should be clearly borne in mind that only part of the very wide subject of the pathology of plants comes under this head, as may be readily seen on comparing the new edition of Frank's "Krankheiten der Pflanzen," which has appeared in the interval, and of which the first volume is devoted to the diseases due to non-living agents, the second to those caused by parasitic plants (not fungi only), and the third to pathological states induced by animals.

Thus comprehensive works on the whole range of this vast subject are not wanting, and the student should observe that the standpoint from which a treatise like this is written differs considerably from those assumed by writers on the general subject of pathology, or those who deal with the morphology and physiology of the fungi.

Berkeley, Frank, Sorauer, and Hartig have shown that the diseases of plants constitute a theme by itself which may be treated with reference either to the symptoms and progress of the pathological conditions, where the victim of disease furnishes the principal phenomena discussed, or to the causes or agents which induce these pathological conditions. These agents may be internal or external, and the latter comprise factors of the non-living environment, or living organisms—animals or plants in anti-biotic relations to the host, or victim.

The present large volume, of more than 600 pages with 330 illustrations, is devoted, as said, to the narrower theme, and bears witness to the astonishing progress made in the study of the parasitic fungi during the last quarter of a century.

Its subject-matter is principally the fungi themselves, and in character it partakes of the nature of a flora or diagnostic list, and a treatise on symptoms and therapeutics, with bibliographical references for those who wish to launch further into this particular arm of the sea of knowledge. It is thus neither a complete treatise on the biology of fungi, nor a detailed work on pathology, but—and in this reside its peculiar characteristics—a volume compiled to meet the wants of an increasing class of students who wish to know something of the parasitic fungi themselves and what plants they attack; something of the mode of attack and the symptoms induced; and something of the suggestions for combating the diseases which have been supplied by experiments in the field. It is thus a typical example of a class of book evolved under the stimulus of the practical spirit of the age, and, in fairness to all be it said, of a high standard of excellence as scientific literature; further, it will be of no use to the crammer, to the examinee, or the dilettante, but must take its place on the shelf of the serious worker, the true naturalist, and the educated cultivator of plants as an indispensable work of reference.

The book consists of two parts, of which the first contains chapters on the nature of parasites and parasitism, the reactions between host and parasite, infection, predisposition, preventive measures, and the economic importance of the diseases of plants, together with a short summary of the facts of symbiosis.

The second, and far larger part, is devoted to a systematic account of cryptogamic parasites—the fungi proper, slime-fungi, bacteria and pathogenic algæ being included. The system followed is that of Brefeld, the saprophytic forms being omitted.

Objection may be made to the inclusion of the algæ and symbiotic forms, such as mycorhiza, the organisms of the leguminous nodules, lichens, &c.; but Tubeuf has something of his own to say about these matters, and although I do not agree with his strained attempts to classify the phenomena of saprophytism, parasitism, and symbiosis, and regard his selection and definition of the terms *nutricism* and *individualism* as particularly unfortunate and misleading, I think that he was quite right in discussing these matters here, if only to help in emphasising the real nature of parasitism by contrast.

The author has avoided several pitfalls. It would have been easy to give way to temptations to discuss in detail several disputed points, especially as Tubeuf is himself an investigator with strong views of his own; but it is noticeable throughout that he attempts a fair summary of the published accounts. The fault of over-description has also been wisely and ably avoided, and this, on the whole, without sacrifice of usefulness; though it must be borne in mind that a good deal of preliminary acquaintance with the subject is necessarily demanded from the reader. Again, there is sufficient treatment of theoretical matters to make the book attractive to botanists not specially concerned with pathology in detail, and, further, the hints on practical therapeutics, though necessarily short, appeal to the cultivator himself, and show that the book is designed to help him.

One fault of omission must be mentioned, if only in justice to those who have done good work in this country: the English literature is almost wholly ignored. We hesitate whether to blame the author—who only follows the too common practice of continental writers—or the editor for this. In any case the latter might have included references to Massee's and Somerville's experiments with *Plasmodiophora*, in his notes, to say nothing of other work by English botanists.

A feature in the work, which adds immensely to its value, is the selection of photographic illustrations of the diseased plants themselves, showing how the victims of fungus attacks look. This is as near an approach to taking the student into the field and showing him the disease at work, as can possibly be made in a book; and when we reflect that this—so to term it—clinical study is as important for plant diseases as it is in the case of human diseases, its importance is obvious. Few people are aware how

much there is to be seen and learnt in the natural history of the diseases of forest and field and garden plants, and Tubeuf's examples should stimulate botanists to pay more attention to the subject. It is true the reproductions of the photographs are by means of the detestible "process blocks," which disfigure most of the books of the present age; but I suppose we must agree that the choice lies between these or none, as prices and means go.

It will be evident that the book is too large for even a brief review of more than the principal headings, but there are one or two features of importance which stand forth in salient contrast to anything met with in similar works.

These are signs of the times. One of the most striking is the far too meagre note on "selection of hardy varieties"—the word "hardy" does not accurately translate the original. From all sides we are now hearing that different varieties of vines, potatoes, wheat, &c., show different disease-resisting powers, and Tubeuf says, "An important method for the protection of plants from disease . . . consists in the selection and cultivation of varieties and species of plants able to resist the attacks of parasitic fungi."

The very brief account of what has been done with the vine, and the reference to what has been discovered about wheat, will only leave the reader hungry for more information.

In Eriksson and Henning's exhaustive volume on wheat-rust—to which I can discover no reference here, the author confining his remarks to a note they published last year in the *Zeitschrift f. Pflanzenkrankheiten*—the student will find that as matter of fact some varieties of wheat suffer little, and others much from *Puccinia*; and their extended investigations show that no mechanical theory as yet proposed explains this, but that a complex physiological phenomenon is here before us. They also show that the *Puccinia* of wheat-rust also varies, both morphologically and in its physiological relations to the disease. We have, in short, to face the fact that the culture of wheat-rust (for we do cultivate it), as well as the culture of cereals, result in the variation of both fungus and cereal, and it appears that selected varieties of both arise and are propagated.

Such varieties of parasitic fungi are also known in other groups—*e.g. Peridermium*, *Gymnosporangium*, *Ustilago*, &c.—and Tubeuf gives a short note under the respective heads; and we have several indications that physiological races are as common among parasitic fungi as they are among bacteria.

Clearly it is matter for experimental inquiry how far these variations are independent or concomitant, and it may be considered that one of the strongest reasons for encouraging the carrying out of agricultural experiments on a large scale, and the gathering of statistical results, that scientific men can urge, is the hope that more light will be thrown on the relations of these variations, and that we may succeed in utilising the knowledge in the practical evasion of disease. I remember being strongly impressed, in 1880–81, by the varietal differences between the *Hemileia* on coffee and that on *Canthium* in Ceylon, and even then threw out the hint that the former had been derived from the latter; but the comparative immunity of *Coffea Liberica* as contrasted with *C. Arabica*, suggested that it was not impossible that a disease-resisting coffee should be found.

The subject is complex, and bristles with difficulties; but that is no reason for hesitating as to the experimental inquiry; and indeed it has already been commenced in several countries, as the reports from Australia, America and elsewhere show.

Another feature of interest and importance in Von Tubeuf's book, is the chapter on "preventive and combative measures," involving the treatment of diseased plants by means of chemicals. Here, again, I notice a lack of attention to the English literature: Berkeley, and others of our countrymen, had experimented with sulphur in various forms, long before most of the authorities mentioned had taken the matter up. Still, it is quite true, the introduction of Bordeaux-mixture, and its employment on the enormous scales adopted in France, Australia, America and elsewhere, have taught us much, and suggested more. It is a common mistake to suppose that the intelligent application of remedial measures to plant-diseases does not pay—there are plenty of witnesses to the contrary; but, unfortunately, school and university courses generally have allowed of so little attention to the knowledge that must be utilised in carrying out such measures, that even skilled farmers, foresters, and other cultivators of plants, have to enter upon these experiments quite unequipped for carrying them out properly.

Tubeuf's chapter on the "economic importance of diseases of plants" may be cordially—if sadly—recommended to all who are interested in the very necessary extension of technical education by the institution of agricultural schools and colleges. He quotes the losses due to the Californian vine-disease (1892) at 10,000,000 dollars; in 1891 the wheat-rust cost Prussia over 20,000,000*l*., and Australia something like 2,500,000*l*. Even allowing for large exaggerations—though reports from Sweden, India, Ceylon, the West Indies, and elsewhere suggest similarly large losses from fungus epidemics—in these estimates, it is evident that we have here to deal with annual losses of which even a saving of a very few pounds *per cent.* would be worth consideration; and the comparatively meagre experiments to hand hold out hopes of much more considerable saving, if steps are taken in time, with a due and intelligent knowledge of the problems to be faced, and the methods of facing them.

This must suffice for our review of this excellent book, the technical details of which are well treated, of the highest importance, and abounding with interest to the naturalist and botanist, as well as to the technologist and practical cultivator. H. MARSHALL WARD.

CAPTAIN LYONS' REPORT ON THE ISLAND OF PHILÆ.

A Report on the Island and Temples of Philæ. By Captain H. G. Lyons, R.E.; with an Introductory Note by W. E. Garstin, C.M.G. (Printed by order of H.E. Hussein Fakhri Pasha, Minister of Public Works in Egypt, 1897.)

THE proposal to build a dam at Philæ, which was brought before the Egyptian Government a few years ago, at the instance of Mr. Willcocks, of the Irrigation Department of Egypt, will be fresh in the memory of many of our readers, even though the details of the

somewhat acrimonious discussion upon it which followed in the papers have been forgotten. Briefly, the Egyptian Government had been informed by its English advisers that a better regulated and larger supply of water was needed for agricultural purposes in that part of the valley of the Nile which lies between Aswân and the Mediterranean Sea, and steps were at once taken to find out how that supply could be secured. Mr. Willcocks was ordered to seek out a site where a huge dam could be built for the purpose of holding back the water behind it; and after much thought and careful examination of the various possible sites, he decided that the best place was at Aswân, a few miles to the north of the beautiful little island of Philæ. The announcement of this decision was received with astonishment and outcries, for it needed no expert knowledge to see that the carrying out of the scheme meant, practically, the destruction of the monuments upon the island, and the submerging of both it and the greater part of the buildings upon it for a considerable number of weeks each year. When Mr. Willcocks' scheme was put before the public in its entirety, it was seen that he had indeed contemplated this disastrous result with calmness, and that if his superior officers accepted his report, one of the most picturesque spots in Egypt would be turned into a huge reservoir. Thereupon followed vigorous protests in England and other civilised countries, and at length the characteristic English compromise was proposed. As was to be expected, the usual nonsense was talked and written by the irresponsible person and faddist, and even archæologists signed their names cheerfully at the foot of columns of vehement protests filled with loose statements and inaccuracies. There is no blinking the fact that an attempt was being made to destroy a unique and very lovely bit of scenery, but it must at the same time be remembered that the actual needs of an agricultural population of a country have to be considered, even at the expense of the gratification of the æsthetic sentiments of visitors from other countries. Fortunately, when the dispute was hottest, certain irrigation experts discovered that all practical advantages necessary would be secured to the Egyptian farmer if the height of the water in the proposed reservoir was less than that suggested by Mr. Willcocks, and Mr. Garstin was able to modify the scheme in such a way as to reduce it by about twenty-seven feet. So that if the reservoir is ever built, Mr. Garstin promises us that "the greater portion of the ruins on the island will remain permanently above the submerged level."

Having agreed to adopt a modified scheme for the building of the dam and for the formation of the reservoir, it next became the duty of the Egyptian Government to take steps to see that the monuments *in situ* were not destroyed by the water in which their lower courses must stand, and, as a result, it ordered that the foundations of these structures should be examined and reported upon. To carry out this important work Captain H. G. Lyons was appointed, and the handsome volume before us contains the results of his labours at Philæ during the last two or three years. Without going into details, it must suffice here to say that he has carried out his work conscientiously, and that every person who has ever seen Philæ will accord him his heartiest thanks for the splendid series of photographs and plans of the island which accompany his report. But however interesting these may be, they are relatively of small importance beside the facts concerning the foundations of the buildings on the island which he now makes known to the world, and we feel sure that the minds of many will be much relieved thereby. It has long been known that the architects of ancient Egypt gave their finest buildings but shallow foundations; but that this was not universally the case is proved by the Temple of Isis at Philæ, in which the foundations of the main buildings descend to the bed rock, and many will be surprised to learn that there is as great a depth of masonry below the ground surface as there is height above it.

"Even in the case of the great pylon," Mr. Garstin says, "the depth of the foundation is some five metres; so that the masonry already descends below the level permanently saturated by infiltration, and consequently the conditions of equilibrium of the structure will be unchanged, even should the water-level be very considerably raised."

Along with the examination of foundations, Captain Lyons has effected a considerable number of important repairs, which have been unostentatiously carried out; and if the other measures which he recommends be adopted, it seems probable that little or no danger to the temples will exist, even should the water yearly rise and fall around their bases. This is Mr. Garstin's view of the matter, and, after all, he is the responsible person ultimately. Briefly, if the reservoir be made, much of the quay wall will have to be rebuilt, and the underground spaces between the cross-walls, which support the pavement of the west colonnade, and the crypts of the great Temple of Isis will have to be filled up with rough masonry. The picturesque remains of the Coptic village, at Philæ, must, of course, disappear, because the mud-brick walls will not withstand the action of the water; but archæologists have long ceased to expect to find there any Coptic antiquities of importance, and consequently will not grieve overmuch. Satisfactory as Captain Lyons' report is in all respects, we cannot help feeling that Egyptologists will be disappointed at one result—that is, his failure to find the remains of any building older than the time of Nectanebus, the last native king of Egypt, about B.C. 360. This is, of course, not his fault, but one of the early investigators of Egyptian antiquities, mentioned by Lepsius in his "Letters from Egypt" (London, 1853, p. 525), expressly states that the remains of much earlier buildings were found built into the structures of the Ptolemaïc period. That the Egyptians, before the time of Nectanebus, made no use of the island of Philæ, it is impossible to believe, especially as they built edifices upon the neighbouring island of Biggeh. So far back as B.C. 3500 we know that Egyptian officials passed that way on their road south to bring back pygmies for the royal court at Memphis, and all the gifts and tribute from the south must have been carried into Egypt by that way. In the time of the twelfth dynasty, about B.C. 2500, a body of lightly-armed "runners" was attached to the garrison at Aswân, whose duty it was to guard the cataract, and it is hard to think that Philæ did not form a base for operations at this period. About one thousand years

later a temple of Osiris seems to have stood on the island, for a governor of Nubia, called Merimes, cut his name, which is found, along with those of his predecessors and successors, in remembrance of a visit thereto, on rocks on the island of Biggeh (see Brugsch, "Egypt," i. p. 423). In the reign of Rameses II., the builder of the temples at Kalabsheh and Abû Simbel, no mention is made of Philæ, and, curiously enough, no remains inscribed with his prænomen and nomen have been found there. The probable explanation of the silence of the monuments about Philæ is that the island was usually reckoned as a part of Biggeh, and even the Greeks and Romans included both islands in the name of Philæ. Be this as it may, we believe that a temple, or temples, existed at Philæ from the earliest period, and that their remains were removed entirely by those who set up the buildings for Nectanebus and his successors; for, after Captain Lyons' exhaustive survey, it is impossible that any can be found there.

It is now our pleasant duty to call the reader's attention to the series of sixty-seven plates which illustrate Captain Lyons' report, and to fully endorse Mr. Garstin's statement that if the ruins of Philæ were to "disappear to-morrow, the scientific world would still possess a record of each detail of their outline and construction," and we rejoice to hear the promised survey of Nubia has been already begun. Though every intelligent person would view with indignation the slightest damage done unnecessarily to the temples at Philæ, still it must be admitted that antiquarian sentiment should not stand in the way of the prosperity of the country of Egypt. If the scheme of a reservoir at Aswân produces a complete survey of the country for two hundred miles south of it, we may hope that a scheme for a reservoir at Gebel Silsileh will be followed by a complete survey of the country to the north of it. Finally, we congratulate Mr. Garstin and Captain Lyons on the completion of a delicate piece of work, and thank H.E. Hussein Fakhri Pasha for sending forth to the world the results in such a sumptuous form.

ASSAYING IN WORKS LABORATORIES.

Notes on Assaying. By P. de P. Ricketts, E.M., Ph.D., Professor of Analytical Chemistry and Assaying, School of Mines, Columbia University; and E. H. Miller, A.M., Ph.D. of Columbia University. Pp. viii + 311. (New York: John Wiley and Sons. London: Chapman and Hall, Ltd., 1897.)

Recueil de Procédés de dosage pour l'analyse des combustibles, des minerais de fer, des fontes des aciers et des fers. Par G. Arth, Professeur de Chimie Industrielle à la faculté des Sciences de Nancy. Pp. iii + 313. (Paris: G. Carré et C. Naud, 1897.)

THE reissue in a new and enlarged form of Prof. Ricketts' well-known book will be welcomed by all who have used the former editions. As Dr. Miller now assists his chief, the book appears as a new one. It is intended to be used in the laboratories of works where only notes for reference are required, and long and detailed descriptions of well-known operations are unnecessary. The result is that it is written in a crisp and telegraphic style, which should commend itself not only to Americans, but to all busy assayers. On the other hand, students would often require a little supplementary oral teaching to enable them to perform the operations efficiently.

The first part, comprising an account of apparatus, reagents and methods, is good of its kind, although there is little that is new. Regarding litharge, there is a noticeable statement that "it should be free from red oxide of lead, as the latter has the power of oxidising silver and thus causing loss of that metal during the assay." This property, however, is shared by litharge; and it would be interesting if experiments were made showing the relative losses due to the action of the two reagents.

In the part dealing with the fire assays of ores and of bullion, the most interesting sections are those on the assay of gold and silver. The method given of parting the beads from gold ores, by heating them with acid in porcelain crucibles, is seldom used in this country, though it is in general use in America and Australia Its merits are little understood in Great Britain, where it is often adversely criticised. It would appear that no adequate defence of it has yet appeared in print, though it would not be difficult to furnish one. Space forbids any attempt of the kind here. It is sufficient to observe that objections to it have been raised mainly by those who have never tried it, and who do not know how easy it is to obtain exact results by its aid.

The method of assay of gold bullion is described as being that used at the Royal Mint, London, where, the authors imply, the greatest accuracy is obtained. Besides the assay of all metals usually found in ores, an account of qualitative blow-pipe analysis is given, and the whole book is far more complete in its present form than was the case with the previous issues.

M. Arth's book is also one of considerable merit. It is an account of the exact methods of analysis used in iron and steel works in France, and will be useful to the works analyst in all countries. It distinguishes between two kinds of analyses: the one required as a daily control of the works, the other to serve as a basis for experiments or in delicate researches. The rough and ready methods employed for the former purpose are, of course, unsuitable for the latter, and *vice versâ.* Both kinds are described, but the first-named class is undoubtedly the more efficiently treated, the Kjeldahl method for the estimation of nitrogen in fuel being, for example, fully described, and Dumas' method deliberately omitted except by name.

The methods of analysis used in steel works in France do not appear to differ materially from those used in this country, and some which are described were even devised on this side of the Channel. It is evident, therefore, that this book will prove as useful to our analysts as to their colleagues in France.

OUR BOOK SHELF.

Life and Letters of William Barton Rogers. Edited by his Wife, with the assistance of William T. Sedgwick. Vol. i. pp. viii + 427. Vol. ii. pp. vi + 451. (Boston and New York: Houghton, Mifflin, and Co., 1896.)

A TRULY great achievement of the life of William Barton Rogers was the foundation and establishment of the Massachusetts Institute of Technology, which ranks among the best technological schools in the world. His scheme was adopted by a general committee in October 1860, and

it became the basis of the present Institute. If Mr. Rogers had accomplished no more than this, he would yet have done a great service to the cause of science and education. He was, however, an active investigator, and the two volumes before us testify to the keenness of his interest in all scientific subjects.

William Rogers was born in 1804. He became professor of natural philosophy and chemistry at William and Mary College, Williamsburg, Virginia, in 1828, and professor of natural philosophy in the University of Virginia, and director of the geological survey of Virginia, in 1835. He resigned his professorship in 1853, and removed to Boston, where, a few years later, he took the chief part in founding and organising the Massachusetts Institute of Technology. The physical laboratory of the Institute was afterwards given the designation of "The Rogers Laboratory of Physics," in recognition of his services to physical science and devotion to the interests of the Institute. Mr. Rogers was president of the American Association for the Advancement of Science in 1876, and succeeded Prof. Henry as president of the National Academy of Sciences in 1879. He died suddenly in May 1882, while delivering a short address to the students of the Institute of which he was the father.

Prof. Rogers was one of a gifted quartet. His brother Henry became Regius Professor of Natural History and Geology in the University of Glasgow in 1857, and was elected a Fellow of the Royal Society in the following year. To the two brothers William and Henry, geology owes the wave theory of mountain chains—a theory deduced from an extended study of the great Appalachian chain. The eldest of the four brothers, James Rogers, served as professor of chemistry, successively, in the Philadelphia Medical Institute, the Franklin Institute, and the University of Pennsylvania. Upon his death in 1852, the youngest of the brothers, Robert, then professor of chemistry in the University of Virginia, succeeded him in the chair of chemistry at Philadelphia. It was in connection with Robert Rogers that William investigated the solvent action of water—especially when charged with carbon dioxide—on various minerals and rocks.

The wide range of William Rogers' studies and researches, his eminence among men of science in America, his enthusiasm for the advancement of knowledge, and his fraternal affinities, have all assisted in providing material for the two volumes under notice. The memoir is practically filled with letters, only sufficient editorial comment being added to make it a connected history. It would be easy to fill many pages of NATURE with interesting extracts from these letters, but the limitations of space forbid. Naturally the volumes will appeal most to Prof. Rogers' American contemporaries, and to the officers, graduates, and students of the Institute to which they are dedicated. There are, however, many British men of science who will be interested and inspired by this record of his life and work.

L'Ottica delle Oscillazioni Elettriche. By Prof. A. Righi. Pp. vii + 254. (Bologna: Zanichelli, 1897.)

TWO years ago (May 9, 1895) we drew attention to two memoirs by Prof. Righi, who in 1893 succeeded in producing and investigating the behaviour of Hertzian waves only a few centimetres in length. He has now collected the results of these and other researches, which he has made, in the form of a convenient volume, arranged in two parts. The first contains a detailed description of his apparatus, its mode of construction and use, together with the effects which can be produced by it, especially such effects as are easily exhibited by electro-magnetic waves, but only with difficulty by light-waves, on account of the extremely short wave-length of the latter. The second and longer part corresponds more closely to the title of the book, and gives an account of the following phenomena: interference-phenomena with electro-magnetic waves carried out with experimental arrangements which in the main correspond exactly to the well-known optical ones (*e.g.* Fresnel's mirror and the bi-prism); experiments analogous to the interference of light in thin plates; diffraction-experiments; absorption, transparence and opacity; reflection from the surfaces of conductors and dielectrics; experiments in reflection and total reflection which are exact analogues of optical experiments with prisms, lenses and totally reflecting prisms; elliptic and circular polarisation, and double refraction. An appendix contains a series of notes on the theory of electro-optics. The book is well printed and illustrated, and will be welcomed by all who are interested in the development of the work of Maxwell and Hertz. *pv.*

The Concise Knowledge Natural History. Edited by Alfred H. Miles. Illustrated. Pp. xvi+771. (London: Hutchinson and Co., 1897.)

THIS book of less than 800 octavo pages deals with the animal life of the world. The arrangement is systematic; the space allowed to each group is proportioned to its popular interest, and the authors have done what they could under the prescribed conditions to make their contributions readable. Since the Vertebrates occupy more than five-sevenths of the volume, the Invertebrates come off poorly. Mammals, by Mr. Lydekker, and Birds, by Dr. Bowdler Sharp, are more liberally treated, and these sections are far more interesting than the rest. It will be seen that though the book has its merits, its use is limited. We can hardly recommend it to students or to field-naturalists, or to collectors, but it will suit those who desire information about the animals which they meet, not in the flesh, but in the newspaper or book of travel. The quantity and quality of the information are equal to what would be found in any encyclopædia except the Britannica. The cuts, which are numerous, are not good; some of the frogs and salamanders, for instance, are almost unintelligible. There is a full index, which will prove a useful feature. Is it worth while to point out that there is no such plural as *Animalculæ?*

L. C. M.

Through a Pocket Lens. By Henry Scherren, F.Z.S. Pp. 192. (London: The Religious Tract Society, 1897).

GIVE this book to an intelligent boy or girl with a taste for natural history, and let it be used not merely as a reading-book, but as a guide-book to nature study, and you will do more towards cultivating the spirit of investigation than by dozens of lectures. The common idea that very little real work can be done without a compound microscope and numerous accessories has tended to discourage young naturalists, but Mr. Scherren describes so many interesting objects, all of which have been seen by him with a pocket lens, that his book will induce many to study nature who would otherwise acquire knowledge second-hand. All the examples described are taken from the Arthropoda. The group is interesting, and specimens belonging to it are so common that they can easily be procured. We have no doubt that many young students will profit by this instructive introduction to one of the main divisions of the animal kingdom.

The Young Beetle Collector's Handbook. By Dr. E. Hoffman, Curator of the Royal Natural History Museum at Stuttgart; with an Introduction by W. Egmont Kirkby, M.D. Pp. viii + 178. (London: Swan Sonnenschein and Co., Ltd., 1897.)

THIS work contains twenty coloured plates, comprising about 500 figures of Coleoptera, which may certainly, in many cases, prove of considerable service to the young beetle collector; but the letterpress is of comparatively little value, consisting, as it does, mainly of very short and more or less disjointed descriptions of selected

genera and species. In a work with such a title one expects rather to find a detailed description of the methods of procedure as regards capture, habits, habitats, &c., and not to require the young collector to plunge *in medias res* without such knowledge. The introduction certainly attempts to deal with these points, but it only consists of eleven pages of large print; and the all-important subject, in such a work, of "the habits of beetles and how to catch them" is dismissed in about thirty lines.

The plates are worth the cost of the work, which may be found useful for a somewhat more advanced student, but which hardly appears to realise our idea of a "Young Collector's Handbook."

Exercises in Practical Physiology. By Augustus D. Waller, M.D., F.R.S. Part iii. Pp. 91. (London: Longmans, Green, and Co., 1897.)

THE exercises and demonstrations contained in this and the two preceding parts are primarily intended to facilitate class work in physiology, and for use in conjunction with such a text-book as the author's "Introduction to Human Physiology." The present part contains sixty-eight instructive experiments on the physiology of the nervous system, and descriptions of the instruments used in investigations in electro-physiology generally. The subject is one which the author has made peculiarly his own; so that the experimental details will be found sufficient to enable students and demonstrators to set up the required apparatus satisfactorily and obtain good results. The book affords a strong argument for the teaching of the principles of physics to students of physiology; for without this fundamental knowledge it would be impossible to perform the experiments intelligently.

Year-Book of the Scientific and Learned Societies of Great Britain and Ireland. Fourteenth annual issue. Pp. 270. (London: Charles Griffin and Co., Ltd., 1897.)

THIS work, in addition to being a convenient handbook of our scientific societies, contains lists of the papers read during 1896 before societies engaged in fourteen departments of research. It is thus a very useful index to scientific progress, as well as an indispensable book of reference to the officers, places and times of meetings, publications, and membership fees, of British Societies for the advancement of knowledge of every kind.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Trotting Horse.

IN "The Primary Factors of Organic Evolution," Prof. Cope, whose recent death has taken from us an untiring worker and suggestive writer, adduces the evolution of the trotting horse as an illustrative case of the inheritance of characters due to the exercise of function (p. 426). Prof. Brewer, of Yale, is quoted at some length. He says: "There is every appearance and indication that the changes acquired by individuals through the exercise of function have been to some degree transmitted, and have been cumulative, and that this has been one factor in the evolution of speed. . . . There is nothing whatever in the actual phenomena observed anywhere along the line of this development of speed that would lead us to even suspect that the changes due to exercise of function had *not* been a factor in the evolution, and there is not a particle of evidence, other than metaphysical deductions, much less proof, that it would or could have gone on just the same by mere selection and adventitious variation" (pp. 429–430).

Mr. A. J. Meston, of Pittsfield, Mass., has recently discussed this question statistically in a pamphlet entitled "The Common Sources of 2·10 trotting and pacing speed." The results of this seemingly very careful investigation are of such general biological interest, that I have no hesitation in requesting space to draw attention to Mr. Meston's conclusions.

The first point that is especially noteworthy is the predominant influence of one horse, Hambletonian 10 (1849–1876). "While we have extreme speed without the aid of Hambletonian, it is, nevertheless, a fact that the influence of Hambletonian has been exerted amongst 92 per cent. of the 2·10 trotters, and 84 per cent of the 2·10 pacers [that is to say, trotters or pacers who can cover a mile in two minutes and ten seconds or under] We have pacing speed, apart from Hambletonian, within two seconds of the best record; but trotting speed without Hambletonian is four seconds behind the fastest mile. No mile has yet been trotted faster than 2·07¾ without the aid of Hambletonian. . . . Furthermore, the majority of both the trotters and pacers that descend from Hambletonian have more than one cross of his blood. . . . A very superficial examination of the blood of the 2·10 list shows that Hambletonian has exerted a predominant influence in its formation" (pp. 6–7).

The second point is the conclusion to which Mr. Meston is led with regard to the transmission of acquired speed. "It appears from the table," he says, "that some stallions and mares, after having been trained to fast records, have got foals that made fast records. It also appears that demonstrated capacity for speed and the ability to beget speed are qualities possessed in common by many stallions and mares, but the relative dates of 'making the record' and 'getting the foal' exclude the affirmation, if not the probability, of cause and effect between the two occurrences. It does not appear that a line of trained ancestors is more successful in producing speed than a line of untrained ancestors, or a mixed line of trained and untrained ancestry. Therefore, the evidence is negative upon the question whether increase of speed acquired by the individual through training, habit, or experience, is passed on to the foal, in any degree, by the force of heredity. On the other hand, the evidence is positive and convincing that congenital capacity for speed and innate plasticity for the development of speed are transmitted hereditarily to progeny, and that, by judicious or fortunate crossing, the capacity and plasticity have been vastly increased" (p. 23).

As this is the most careful statistical investigation of the kind with which I am acquainted, it appears to me that Mr. Meston's conclusions (which, he informs me, were not those that he anticipated at the outset of his inquiry) are worthy of careful consideration. C. LLOYD MORGAN.

Bristol.

Fire-fly Light.

IN *Wiedemann's Annalen* for December last, Prof. H. Muraoka published an account of the rays which he found to be emitted by a fire-fly (described by him as a "Johanniskäfer"), and which resemble the rays which Dr. Dawson Turner has found to be emitted by glow-worms, in that they can pass (like Röntgen's rays and uranium rays) through aluminium. Can any reader of NATURE state what species of insect is known by this name? Muraoka describes them as on the average 13–15 mm. long; the largest being 20 mm. long. He says they have two (or in smaller insects three) rows of luminous spherules on the under side of its body, but that the whole body is photographically active. He used about 1000 insects at a time, with exposures of two to three days.

June 6. SILVANUS P. THOMPSON.

THE LIQUEFACTION OF FLUORINE.[1]

THE physical properties of a large number of mineral and organic fluorine compounds led to the theoretical prediction that the liquefaction of fluorine could only be accomplished at a very low temperature.

Whilst the chlorides of boron and silicon are liquids at the ordinary temperature, the fluorides are gaseous, and well removed from their boiling points. The same difference is noticeable in their organic compounds,

[1] "On the Liquefaction of Fluorine," by H. Moissan and J. Dewar. (Translated from *Comptes rendus* of the Paris Academy of Sciences, May 31, p. 1202).

ethyl chloride boiling at 12°, ethyl fluoride at −32°, propyl chloride boiling at +45°, ethyl fluoride at −2°.

Similar observations have been previously made by Paterno and Oliveri, and by Vallach and Heusler. These facts can also be connected with the experiments of Gladstone on atomic refraction. Finally, although clearly a member of the chlorine group, fluorine in some of its properties also presents some analogies to oxygen. The whole of these observations appear to clearly establish that fluorine would only with difficulty be reduced to a liquid, and it has already been shown by one of us that at −95°, under ordinary pressure, it does not change its state.

In the new experiments that we now publish, the fluorine was prepared by the electrolysis of potassium fluoride in solution in anhydrous hydrofluoric acid. The fluorine gas was freed from the vapours of hydrofluoric acid by passing it through a small platinum spiral cooled by a mixture of solid carbon dioxide and alcohol. Two platinum tubes filled with well-dried sodium fluoride completed this purification. The liquefaction apparatus consisted of a small cylinder of thin glass, to the upper part of which was joined a platinum tube. The latter contained another small tube of the same metal. The gas to be liquefied arrived by the annular space, passed into the glass bulb, and passed out again by the inside tube. This apparatus was united to the tube which led in the fluorine.

In these experiments we have used liquid oxygen as the refrigerating substance. This oxygen was prepared by the methods described by one of us, and these researches have necessitated the employment of several litres of this liquid. The apparatus being cooled to the temperature of quietly-boiling oxygen (−183°), the current of fluorine gas passed into the glass bulb without liquefying; but at this low temperature the fluorine had lost its chemical activity, and no longer attacked glass.

If now the pressure on the boiling oxygen be reduced, it is seen, as soon as rapid ebullition is produced, that a liquid trickles down the walls of the glass bulb, whilst no gas issues from the apparatus. At this moment, the exit tube is closed with the finger to prevent the entrance of any air. Before long the glass bulb becomes filled with clear yellow liquid possessing great mobility. The colour of this liquid recalls the tint of fluorine seen through a layer a metre thick. According to this experiment, fluorine becomes a liquid at about −185°. As soon as the little condensation apparatus is removed from the liquid oxygen, the temperature rises and the yellow liquid begins to boil, furnishing an abundant evolution of a gas which presents all the energetic reactions of fluorine.

We have taken advantage of these experiments to study some of the reactions of fluorine upon bodies maintained at very low temperatures. Silicon, boron, carbon, sulphur, phosphorus, and reduced iron, cooled in liquid oxygen, and then projected into an atmosphere of fluorine, do not become incandescent. At this low temperature, fluorine does not displace iodine from iodides. Its chemical energy, however, is still sufficiently great to decompose turpentine or benzene with production of flame even at −180°. It would seem that the powerful affinity of the fluorine for hydrogen is the last to disappear.

Finally, there is one other experiment that we ought to mention. When a current of fluorine gas is passed into liquid oxygen, there is rapidly produced a white flocculent deposit, which soon settles at the bottom of the vessel. If the mixture is shaken and poured on a filter, this precipitate is separated. It possesses the curious property of deflagrating violently as soon as the temperature rises. We are pursuing the study of this compound, as well as that of the liquefaction and solidification of fluorine, in which further experiments are required.

A NEW DETERMINATION OF THE GRAVITATION CONSTANT AND THE MEAN DENSITY OF THE EARTH.

An account of a new determination of these quantities, carried out in a very careful manner by Dr. C. Braun, S.J., at Mariaschein in Bohemia, has just been published in the *Memoirs* of the Vienna Academy (Bd. lxiv., Math. Nat. Classe).

Dr. Braun has been engaged on the work since 1887. He used the torsion-rod method, and though his apparatus was considerably larger than that of Prof. Boys, it was still much smaller than the older apparatus of Cavendish, Reich, or Baily. The rod was about 24 cm. long, and was suspended from a tripod by a brass torsion wire, nearly 1 metre long and 0·055 mm. in diameter. The whole torsion arrangement was under a glass receiver, about a metre high and 30 cm. in diameter, resting on a flat glass plate. The receiver could be exhausted, and in the later experiments the pressure was about 4 mm. of mercury, and the disturbances due to air currents were very greatly reduced. The attracted masses at the end of the rod were gilded brass spheres, each weighing about 54 grammes. Round the upper part of the receiver, and outside it, was a graduated metal ring, which could be revolved about the axis of the torsion wire, and from this were suspended, about 42 cm. apart, the two attracting masses. Two pairs were used: one a pair of brass spheres about 5 kgms. each, the other, a pair of hollow iron spheres, filled with mercury, and weighing about 9 kgms. each.

To determine the position of the torsion-rod, a mirror was fixed on the centre of the rod, and immediately in front of it was a mirror at 45° to the horizontal, throwing the reflexion down through the base plate on to the horizontal objective of the observing telescope; another mirror, immediately under the lens, was inclined at 45°, and sent the beam horizontally on to a graduated glass scale in the focal plane of the eyepiece. The object of which the image was viewed was an index mark on a plate placed horizontally just below the scale, and the light from it was made to traverse the axis of the telescope outwards by reflexion at a parallel plate of glass at 45° to the horizontal. As the index mark was nearly at the same distance from the objective as the scale, the rays fell nearly parallel on to the torsion-rod mirror, and the angular value of the scale divisions was determined from their length and the distance of the scale from the objective. It was also determined by a theodolite, viewing the scale through the object-glass, and found to be about 3½ min.

The instrument was fixed on a stone slab, in the corner of a room with very solid walls, and protected from temperature variations and electrical effects by a casing of cloth and tinplate.

As there was a continuous creep of the torsion-rod in one direction, amounting in the course of years to several lengths of the scale, it was necessary to have some method of moving the torsion-head. This was effected from outside the receiver in a very ingenious manner. A plate was fixed on a part of the torsion-head which did not revolve, and to this was attached a clock from which the escapement was removed, and on the axis of the escapement-wheel was fixed a small magnet. On the axis, where the driving spring had been, a pinion was fixed, gearing with a large wheel attached to the torsion-head. The magnet could be turned round by moving a magnet outside the receiver, and so the torsion-head could be slowly revolved. The gearing-down was such that, if the minute finger of the clock moved one minute, the image of the index in the telescope moved one scale division.

Vibrations of the torsion-rod were started by a light magnetised fork, which could be made to softly touch the rod on either side by the motion of a magnet outside the receiver.

The moment of inertia of the rod was determined, both by calculation and experiment, with very satisfactory agreement, and all the linear measurements of the apparatus, and of the distances, were made very carefully by horizontal and vertical cathetometers. Ingenious reflexion devices were used for measurements, which were made through the walls of the receiver.

Dr. Braun used both the deflexion method of Cavendish, and the oscillation method first used by Reich, to whom it was suggested by Forbes. In the deflexion method the attracting masses are placed outside the case, in such positions that their pulls on the attracted masses twist the rod round. The deflexion is observed, and the value of the corresponding torsion couple is determined by the time of vibration of the system. When the rod is deflected it does not, of course, take up its new position in a "dead beat" manner, but oscillates about it. The usual method of determining the centre of swing has been to observe successive elongations or turning-points, and by combining these in threes to eliminate the effect of decrement, and so to deduce the centre. But Dr. Braun found the centre more accurately by observing the times of transit of several scale divisions near the centre, in both directions. By interpolation he could determine the point about which the time of oscillation in either direction was the same, and this was taken as the centre of swing. The deflexion observed was about 13 divisions of the scale. The times of transit were registered on a chronograph.

The wire showed a certain amount of elastic after-action, and by subsidiary experiments on a similar wire this was as far as possible allowed for.

In the oscillation method the attracting masses are placed in a line with the torsion-rod, one at each end. Their attractions then act, not to deflect the rod, but to increase the restoring force, and so to lessen the time of vibration. The attraction is determined by comparing the times of vibration when the masses are in position, and when they are removed, or when they are placed so that the line joining their centres is at right angles to the rod.

The time of vibration observed by Dr. Braun was about 1275 seconds, and when the masses were put in position this was altered by about 46 seconds.

The results obtained in the years 1892 and 1894 were finally used, and these gave for the mean density of the earth—

	1892		1894
Deflexion method	5·529	...	5·526
Oscillation ,, ...	5·520	...	5·531

Giving due weight to the various observations, the final result is practically identical with that of Prof. Boys', viz.:

$$\text{Mean density} = 5{\cdot}52725 \pm {\cdot}0012$$
$$\text{Gravitation constant } G = 665{\cdot}786 \times 10^{-10}$$

J. H. P.

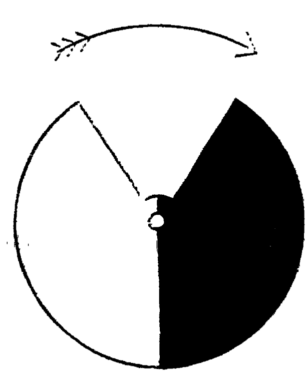
SUBJECTIVE TRANSFORMATIONS OF COLOUR.

IN a communication to the Royal Society on May 13, I described some curious experiments, showing how coloured objects might apparently be made to assume tints which were complementary to their actual hues—red, for example, appearing as green or greenish-blue, and green as pale red.

The phenomenon depends upon the rapid generation of negative after-images of the kind demonstrated by the familiar experiment with the red "wafer." If a red wafer lying upon a sheet of white paper is looked at steadily for about half a minute, and the gaze is then suddenly transferred to some other part of the paper, a greenish-blue ghost of the wafer will be seen. The portion of the retina upon which the red image at first falls becomes fatigued and partially insensible to red light; it is therefore unable to appreciate the red component of the white light afterwards reflected to it, and the sensation of the complementary colour consequently predominates.

The new experiments indicate that the preliminary stare may, under certain conditions, be an exceedingly brief one. In a paper published three years ago (*Proc. Roy. Soc.*, vol. lvi. p. 132) I called attention to an observation indicating that a short period of darkness imparts to the retinal nerves a degree of sensitiveness, which is far above the normal average in the light, and which quickly passes away again under the influence of illumination. This peculiar sensitiveness is in fact both acquired and lost in a small fraction of a second, and is therefore very favourable for the rapid production of negative after-images.

Let two small screens—one black and the other white—be held together in one hand, and arranged so that there may be a triangular gap between them. Let the black screen first cover the paper upon which the wafer is lying; this will darken a portion of the retina, and render it sensitive. Then let the screens be quickly moved sideways, so that the wafer may for a moment be exposed to view through the gap, the movement being stopped as soon as the paper is covered by the white screen. A bright but evanescent greenish-blue ghost will succeed the red impression. But the curious thing is that if the illumination is strong, and the screens are moved at the proper speed, no trace of red will be seen at all; it will appear exactly as if the actual colour of the wafer were greenish-blue. The action of light after a short period of darkness seems to have the power of appreciably diminishing the sensibility of the retinal nerve-fibres in a space of time so short, that if the light be coloured its colour is not consciously perceived. I am informed that analogous phenomena have been observed in other branches of physiology; a well-defined reaction sometimes occurs when no direct evidence can be detected of the existence of the excitation to which the reaction must have been due.



By the use of a rotating disc having a black and white[1] surface and an open sector, as in the annexed figure, the effect can be shown continuously. The disc is made to turn some six or eight times in a second, while its front surface is strongly illuminated either by bright diffused daylight or by a powerful lamp. An incandescent lamp of 32 candle-power at a distance of six inches gives excellent results; it should be placed opposite the disc, and should be provided with a small tin reflector to protect the eyes from the glare. A red card placed behind the disc is made to appear green, a green card pink, and a blue one yellow, while a black patch painted upon a white ground appears whiter than the ground itself. At the conversazione of the Royal Society on May 19, I exhibited some designs which had been prepared for the purpose of demonstrating the phenomenon in a striking manner. Among them was a picture of a lady with indigo-blue hair, an emerald-green face, and a scarlet gown, who was represented as admiring a violet sunflower with purple leaves. Seen through the disc the lady's tresses appeared flaxen, her complexion a delicate pink, and her dress a light peacock-blue, while the petals of the sunflower became yellow and its leaves green. Other designs showed equally remarkable transformations of colour.

SHELFORD BIDWELL.

[1] A pale brownish-grey tint is better than pure white.

INTERNATIONAL CONGRESS ON TECHNICAL EDUCATION.

THE fourth meeting of the Congrès Internationale de l'Enseignement Technique, to be held this year in London, on the invitation of the Society of Arts and the Worshipful Companies of Mercers, Fishmongers, Drapers, Goldsmiths, Merchant Taylors, Vintners, Clothworkers, Leathersellers and Carpenters, will be opened on June 15 by an address from the President, the Duke of Devonshire, and from the President of the last Congress, Mr. Léo Saignat.

This meeting of Congress, the previous meetings of which were—in 1886 (at Bordeaux), in 1889 (at Paris), and in 1895 (at Bordeaux), appears likely, if one may judge of the interest it is exciting, to be a success.

Invitations were sent through our Foreign Office to Foreign Governments to appoint delegates, and up to the present notice has been received of the appointment, by Belgium, of M. Eugène Rombaut, Inspector-General of Industries and Professional Education, M. Wanters, Assistant Inspector, and Dr. Pyffersen, of the University of Gand, and, by France, of M. Félix Martel, Inspector-General of Public Instruction. Invitations have also been sent to the Technical Instruction Committees of County Councils, and other bodies and institutions interested in the subject, to appoint representatives, and have met with a hearty response; also to bodies and institutions abroad of a like character, in which case an equally satisfactory result is expected.

There are also a large number of persons who, by the payment of the modest subscription of 5*s*., have become members of the Congress, and as such are entitled to all the privileges of the Congress.

After the opening addresses, the Congress will break up into two Sections—the subjects to be discussed, which have reference only to advanced and secondary instruction, falling under the heads of Industrial and Commercial Education—to meet simultaneously from 11 to 1 and 2.30 to 5 each day; one at the Society of Arts, the other at the London School of Economics, until Friday, at 2.30, when there will be the concluding meeting of the combined Sections. The list of those who have up to the present promised papers, so far as this country is concerned, is decidedly a strong one, containing, as it does, the names of Sir J. Donnelly and Sir H. T. Wood, who will deal with the part taken by the Society of Arts in the matter of technical education; Dr. Wertheimer and Mr. Dixon, on subject of examinations; and Prof. Ayrton, Mr. Redgrave and Mr. Macan, on State and legislative interference; Sir J. Fitch, Prof. Thompson, Mr. Slingo and Mr. Turner, on reforms and limitations; Mr. Wells, on the training of teachers; Prof. Garnett, Mr. Hogg and Mr. Sachs, on training bodies; Dr. Armstrong and Dr. Gladstone, on chemical education; Mr. Ablett, on drawing; Mr. King and Mr. Swire Smith, on evening schools; and, on the commercial side, Dr. Wormell, Mr. Webb, Mr. Eve, Mr. Hewins, and Mr. Organ. Sir P. Magnus will speak on theory and practice in trade education, and there will be a series of papers from practical men on the subject of technical education as it affects particular industries and agriculture. There will be a joint Indian paper from Mr. Baines and Mr. Bhownaggree, and one each from seven of our colonies by a man of official position and educational experience in the colony to which the paper relates. The ladies will be represented by the Countess of Warwick, on rural districts; Miss Hughes, on technical education of girls and women; Miss Pycroft and Miss Mitchell, on domestic economy; and Miss Calder and Miss Walter, on domestic science.

The list of foreign papers is, as yet, far from complete; but amongst the contributors from abroad may be mentioned, in addition to those already referred to, Dr. Witt (of Berlin), Prof. Lunge (of Zürich), M. Siegfried and M. Mesureur (of Paris), M. Ed. Sève (of Belgium). Arrangements are being made to enable our foreign visitors and others to become acquainted with the work being done in the matter of technical education, and also for their entertainment. Under the last head may be mentioned the evening reception at the Mansion House, on June 17 (to which the Lord Mayor has kindly invited the members of the Congress), the Society of Arts conversazione on June 16, and an excursion for foreign delegates to be arranged on June 19.

JAMES WYLLIE RODGER, A.R.C.S.

BY the death of J. W. Rodger a young life of great scientific promise has been cut short. He was born at Stewarton, N.B., on December 11, 1867, and was educated at Kilmarnock Academy, under Dr. Dickie, and at the Royal College of Science, London. His college career was interrupted by illness, but he won all the chief prizes, and took a very active part in the management of the college societies. In 1889 he was appointed assistant in the research laboratory, with the result that in the course of the next five or six years a number of papers were published, of which he was joint author with Dr. Thorpe. One of the most important of these, "On the relations between the viscosity of liquids and their chemical nature," was printed in the *Philosophical Transactions*, and was the subject of the Bakerian Lecture in 1894. By a kindly arrangement the lecture was delivered by the younger of the two authors, and no one who was present is likely to have forgotten how well Rodger acquitted himself of his task. It was an admirable piece of exposition. He spoke quickly, but with perfect distinctness; with modesty, but without apparent nervousness or hesitation. Every point was made clear, and at the end it was the general opinion that the Bakerian Lecture had rarely, if ever, been better given than by the youngest Bakerian Lecturer.

A continuation of the work on viscosity, by the same authors, appeared in the *Transactions* in March of the present year.

At the end of 1895 another important paper by Rodger and his friend, Mr. W. Watson, was also published in the *Transactions*. The subject was "The magnetic rotation of the plane of polarisation of light in carbon bisulphide and water."

In addition to these labours Rodger wrote often and well in NATURE and in *Science Progress*, chiefly choosing subjects connected with chemical physics.

Of singularly attractive appearance and manners, popular with his fellows, a good teacher, and a first-rate lecturer, he had done enough solid work to prove that, if life and health were spared, he would win an honourable place in the ranks of English science. But it was not to be. Some time ago serious delicacy of the chest developed, and ten days ago he died before completing his thirtieth year.

A. W. R.

NOTES.

AT the annual meeting for the election of Fellows of the Royal Society, held on Thursday last, the candidates whose names and qualifications we have already published (p. 54) were elected into the Society.

THE Vienna Academy of Sciences have elected as foreign members: Profs. Vogel and Bezold of Berlin, Prof. Gegenbaur of Heidelberg, Prof. Max Müller, and Lord Lister.

THE President and Council of the Royal Geographical Society will hold a reception at the Natural History Museum this evening.

THE French Association for the Advancement of Science will hold its twenty-sixth meeting at Saint Étienne on August 5–12, under the presidency of M. Marey.

MR. PERCY S. PILCHER has invited a number of friends and persons interested in aerial navigation to witness one of his experiments with a soaring machine at Upper Austin Lodge, Eynsford, Kent, on Saturday afternoon, June 19.

THE important discovery by two Japanese botanists, of the existence of spermatozoids in certain flowering plants (*Ginkgo biloba* and *Cycas revoluta*), has already been recorded in the pages of NATURE (vol. lv. p. 396). Original preparations, by Prof. Ikeno and Dr. Hirase, illustrating their discovery, will be exhibited by Dr. D. H. Scott, F.R.S., at the next meeting of the Linnean Society, on June 17. This will be the first occasion on which this remarkable observation, obliterating one of the chief supposed distinctions between Phanerogams and Cryptogams, has been demonstrated to European botanists.

THE annual meeting of the Iron and Steel Institute will be held at Cardiff on August 3–6, under the presidency of Mr. Edward P. Martin. A detailed programme will be issued when the arrangements are further advanced.

THE Croonian Lectures of the Royal College of Physicians will be given by Dr. Hale White, at the Examination Hall, on June 15, 17, 24, and 29. The subject of the lectures is "The means by which the temperature of the body is maintained in health and disease."

THE forty-second annual exhibition of the Royal Photographic Society will be held from September 27 to November 13. Negatives, transparencies, photo-mechanical prints, stereoscopic work, photographs of purely scientific interest, and photographs coloured by mechanical means will be admitted to the exhibition, and medals will be awarded by the Judges. Exhibits must reach the Secretary of the Society, 12 Hanover-square, London, W., on or before September 8.

WE regret to have to record the following deaths:—Dr. Julius von Sachs, Professor of Botany in Wurzburg University, and Foreign Member of the Royal Society; M. Slouguinoff, Director of the Physical Institute of the Imperial University of Kazan; Mr. H. B. Chamberlin, who presented the Chamberlin Observatory to Denver University, and in other ways assisted in the advancement of science; Mr. William Godward, formerly of the Nautical Almanac Office, and author of some useful astronomical tables; M. Manen, Correspondant of the Section of Geography and Navigation of the Paris Academy of Sciences; and Baron Oscar Dickson, who fitted out several Arctic expeditions, including the Vega expedition of Baron Nordenskiold.

THE organisation and federation of local scientific societies is a work well worth doing. Prof. Meldola pointed out in these columns a year ago (vol. liv. p. 114) how science would be better served if the efforts of the legion of amateur naturalists were co-ordinated by the formation of groups of societies. The South-eastern Union of Scientific Societies is a group of this character, and the success of the congress which the Union held at Tunbridge Wells towards the end of last month, under the presidency of the Rev. T. R. R. Stebbing, F.R.S., will, we hope and believe, lead to the federation of other local societies. The societies which have joined the Union are almost exclusively natural history societies. They are friendly to philosophy and literature, to mathematics and chemistry, to agriculture and political economy, to astronomy and the use of the globes; but they find their own more special and serious employment in zoology, botany, and geology. What the British Association does on an imperial scale, the Union hopes to do for a limited area. The pursuit of natural knowledge will thus be encouraged, the results of investigations will be made more widely known, and, best of all, public opinion will be enlightened as to the value of scientific work.

NOTHING is worse than fog at sea. A storm may cause discomfort, an accident may cause delay, but in neither case does the traveller feel so helpless as when his vessel is completely shut in by a dense fog. To lessen the danger which then exists, Prof. E. C. Pickering, the Director of the Harvard College Observatory, suggests, in a pamphlet just received, a method of determining the position of a vessel in a fog, based upon the velocity of sound. If two fog-horns of different pitch be placed at equal distances from the middle of a channel or entrance to a harbour, and be sounded simultaneously at regular intervals of about a minute, it will be evident that a captain of a vessel will be able to locate his position with fair accuracy by noting when the sounds of the horns are heard. If the two sounds are heard at the same instant the vessel will be in the middle of the channel, and if they are heard after one another it would be possible to judge from the interval between the two how much the vessel is out of the middle of the channel. For vessels passing one another, Prof. Pickering suggests that each should whistle or blow the horn or syren as soon as the sound is received from the other vessel. Then, if they are five miles apart, each will whistle every fifty seconds, and the distance in miles between the two vessels can always be determined by dividing the interval in seconds by ten. By placing two different fog-whistles on a long steamer, one at the bow and the other at the stern, and arranging that the sounds emitted by both should be heard together by an observer standing at the bow, many collisions might be prevented. Instructions could be given to sailing vessels to keep quiet so long as both signals were heard separately, for they would then be in no danger, but to fire a gun or make other loud noise when both whistles were heard together, for they would then be in front of the steamer. These various methods may be combined indefinitely, and they seem to be worth the consideration of navigators.

AN appeal is being made to iron-masters of the various important iron-making countries for annual subscriptions towards the maintenance of a central laboratory for the testing of iron and steel, to be founded at Zürich under the auspices of the International Society for Testing of Materials of Construction. The Society was founded at a congress held at Zürich in 1895, and none of the tasks which it has imposed upon itself are of greater importance, while none present greater difficulties, than the unification of the methods for the chemical analysis of iron and steel. Efforts have been made in several countries for some years past to lay the foundations of a better knowledge of this subject. But whilst to the fullest extent recognising the very great value of the work already done locally, the Council of the International Society decidedly believes that the work hitherto done in many isolated places should be brought together in a common focus where it would be classified, compared, and reduced to a common standard. Such a central laboratory would also have the task of following the progress of both industry and science, of examining all new methods of any importance brought forward in various quarters, of searching for new methods whenever new problems were presented, and of serving as a guide to the individual chemists when they were beset by the difficulties inseparable from their avocation. Zürich has been chosen as the seat of the institution; and ample accommodation has been secured in the magnificent chemical laboratory of the Federal Polytechnic School. The Federal Council has granted the use of these rooms, free of rent, for the projected central laboratory. Hans von Jüptner, chief chemist of the Neuberg Iron and Steel Works in Austria, has been appointed as the head of the laboratory. 2000*l.* per annum is

required for the maintenance of the laboratory, and it would be impossible to start the laboratory unless this amount was secured for, say, ten years. Looking at the immense importance such a central laboratory is likely to acquire for the whole of the iron industry, and the very large pecuniary benefit ultimately following therefrom, there should not be much difficulty in obtaining promises of subscriptions to the amount required. Mr. Bennett H. Brough, the Secretary of the Iron and Steel Institute, has undertaken to receive subscriptions, and to forward them to the International Society.

FOR a period of about eight years a portion of the staff of the Meteorological Office has been busily engaged in the discussion of observations for the preparation of Monthly Current Charts of the Atlantic Ocean. The observations are contained in about 5500 logs, principally of merchant vessels, collected by the Meteorological Office since the year 1854, and about 13,000 logs kept on board H.M. ships since 1830. The charts for six representative months, referring both to the North and South Atlantic, have been prepared for publication under the superintendence of the Hydrographer of the Admiralty, and are issued in the form of Admiralty charts. They bring to light various interesting points which are masked by charts referring to longer periods; for instance, the Gulf Stream, from which this country is supposed to derive much of its warmth in winter, is shown to flow with varying velocity according to the season, the rate being about 100 miles a day in June, in the Straits of Florida, while in October and November it does not exceed 70 miles a day, and at times only amounts to about 20 miles; and the Guinea and equatorial currents are shown to undergo considerable variations according to the time of the year. Generally speaking, the oceanic circulation can now be studied in a manner that was not possible before the publication of monthly charts, and the results cannot but prove to be of the greatest utility both to seamen and men of science.

MR. H. C. RUSSELL, Government Astronomer of New South Wales, has published, in a recent number of the *Proceedings* of the Royal Society of that colony, a chart showing the tracts of 154 current papers collected during the past two years. The lines plotted on the chart are the shortest tracks between the points where the bottles were thrown into the sea and where they were found. The routes taken by the bottles are interesting: most of them were found on the coast between Melbourne and Adelaide; fifteen were picked up on the east coast of Australia—three of these went to the south, eight went to the north, and four came in from the east. Mr. Russell remarks that, in view of the well-known southerly current on this coast, it is remarkable that so few of the papers seem to go with it, and that the majority of the papers found go against it. The prevailing wind seems to have a decided action in the direction of the drift of the bottles. Three papers, thrown overboard off Cape Horn, followed nearly the same tracks; one was picked up on the west coast of Australia, and the others on the coast of Victoria: their daily rates, over a distance of about 9000 miles, being 9·0 miles, 7·9 miles, and 10·3 miles respectively.

AN interesting collection of prehistoric flint instruments which Mr. H. W. Seton-Karr discovered in Egypt last November, and which he believes to come from the lost flint mines of Egypt, was recently exhibited by him at the Royal Archæological Institute. The collection also included a number of specimens of what Mr. Seton-Karr considers to be the most perfectly preserved palæoliths hitherto discovered. The flint mines are situated in the Eastern Desert of Egypt, some at a distance of about 30 miles from the Nile, some nearer, in the Wady-el-Sheik district. Of palæolithic implements of the earliest date he found but two at the mines. The remainder came from Abydos, Nagada, Nagh Hamadi, Thebes, and other places in the Western Desert. At some of the mines were shafts about 2 feet in diameter, filled up with drifted sand, and surrounded by masses of excavated rock neatly arranged. There was usually a central work-place where most of the objects were discovered. But in some mines a number of clubs or truncheons lay distributed uniformly, as though hurriedly left when the mines were last abandoned, at a period probably long anterior to historic record. The results of Mr. Seton-Karr's sixth and latest expedition were shown in the implements of flint and quartzite from Somaliland. With respect to these discoveries, Sir John Evans remarked in a communication made to the Royal Society, that they "have an important bearing on the question of the original home of the human race. Of their identity in form with some from the valley of the Somme and other places there can be no doubt, and we need not hesitate in claiming them as palæolithic. The cradle of the human race must have been situated in some part of the world where the climate was genial and means of subsistence readily obtained."

IT is depressing to think that there exist not only private persons, but public bodies who put more trust in the wild assertions of charlatans than in the matured conclusions of science. The latest instance of gullibility of this character comes from Bedfordshire. The Urban District Council of Ampthill were ordered by the Local Government Board to procure a water supply within a limited time, the Council being given a free hand how to go to work, and they thereupon unanimously resolved to employ a water diviner. Accepting the recommendations of this gifted gentleman, the District Council applied for a loan to carry them out. But, fortunately for common-sense, when the Government auditor recently sat to audit the accounts of the Urban District Council of Ampthill, several ratepayers raised objections to an expenditure incurred in the employment of the water diviner. They produced geological plans and sections to show that, if the diviner's recommendations were acted on, the Council would be boring into a stratum of Oxford clay, the depth of which had not been fathomed as yet, although a boring had been made to 700 feet, and no water obtained. The auditor, in announcing his decision to disallow the payment, stated that in seeking for water the District Council had disregarded the reports of experts, and had gone for guidance to a man who had a reputation for discovering water by some unusual and peculiar method not possible to ordinary persons, and the question he had to settle was whether this was legal or not. Money might properly be spent on experimental borings under proper advice, but it had not been proved that the diviner employed had any greater power than any one else. It had been held that "the pretence of power, whether moral, physical, or supernatural, with intent to obtain money, was sufficient to constitute an offence within the meaning of the law," and he, therefore, thought that, as the diviner claimed to exercise some such power, his employment was clearly illegal, and the amount of his fee would, therefore, be disallowed, and the gentlemen who authorised the payment surcharged with it. The decision will assist, perhaps, in reducing the number of believers in the water diviner's art.

FOR those men of science who may be induced to travel over Siberia, now that they can do it by rail, we notice that a new interesting museum is being opened at Chita, the chief town of Transbaikalia, in connection with the Transbaikalian Section of the Russian Geographical Society. Rich collections relative to Buryate buddhism, and good collections of objects belonging to natural sciences, archæology, and occurrence of gold in mines, rapidly accumulate in that new little museum, to which a botanical garden is to be annexed.

THIS year's exhibition of the Russian Archæological Commission at St. Petersburg, containing the collections made in the years 1895 and 1896, offers a special interest. Besides a great number of most valuable classical antiquities discovered at the sites of old Greek colonies on the Black Sea, it contains very interesting collections of stone-age implements and pottery from Kieff, Tiflis, and Poland; of the intermediate age between the stone and the bronze period from various parts of Central Russia; and very rich collections of bronze weapons and implements from Caucasia, Saratoff (a splendid bronze helmet), Tomsk, and Yeinseisk. Among these latter the miniature copies of various implements of that period deserve a special mention.

THE last number of the *Journal of the Russian Physical and Chemical Society* (xxix. 3) contains an obituary notice, devoted to the memory of Dr. Véra Bogdanovskaya-Popoff, who was killed on May 8 in her own laboratory at Izhora, by an explosion. She had been working to obtain a combination, analogous to prussic acid, in which nitrogen would be substituted by phosphorus. When Mlle. Bogdanovskaya came to Geneva, in 1890, to study under Prof. Groebe, she intended to carry on that investigation, but was dissuaded by Prof. Groebe, and made, instead, a research on dibenzyl ketone (*Chemische Berichte*, xxv., 1892), for which she received at Geneva the degree of Doctor of Sciences. Returning to Russia in 1892, she was assistant to Prof. Lvoff, at the High Courses for Ladies, and devoted much of her time to aid the beginners in grasping the principles of chemistry. She lectured also upon stereo-chemistry, which she had studied under Prof. Guye; and finally, in her own laboratory in the neighbourhood of St. Petersburg, returned to the work on the phosphorus analogues of prussic acid. She fell a victim of an explosion which took place during that dangerous investigation.

AMONG recent American botanical papers received are "New Studies upon the Smut of Wheat, Oats, and Barley," issued from the Government Agricultural Experiment Station for North Dakota; and the completion of Dr. Millspaugh's "Contributions to the Coastal and Plain Flora of Yucatan," published by the Field Columbian Museum.

THE Deutsche Seewarte has just issued a volume entitled "Segelhandbuch" for the Pacific Ocean, intended to accompany the Atlas of Charts for that ocean, which appeared some time ago. The work is divided into a large number of chapters, written by the staff of the Seewarte and other experts, and contains the results of experience gained by the discussion of an immense number of trustworthy observations, mostly made on board German vessels, relating both to air and sea. The Seewarte has now issued these useful atlases and handbooks for all the large oceans.

IN a recent number of the *Proceedings* of the Boston Society of Natural History Mr. Gerrit S. Miller, jun., gives an account of the mammals of Ontario, based on collections made in different parts of that province in 1896. To these are added notes on the same subject, made by Mr. Allan C. Brooks during ten years' residence in the counties of Wellington and Hamilton. While we fully allow that science is cosmopolitan, it could be well wished that our Canadian friends would pay a little more attention to the fauna of their own country, and not suffer it to be entirely in the hands of their more active brethren of the United States. We trust that the proposed establishment of a Professorship of Zoology at McGill University, Montreal, may have a good effect in this direction.

THE last number of the *Annali d'Igiene Sperimentale* contains a paper by Dr. Massone, on the presence of tubercle bacilli in the milk supplied in Genoa. Forty-four different samples of milk were collected, and were submitted to a careful microscopic examination, but in no case were tubercle bacilli discovered. When, however, the further test was employed of first submitting the various milk samples to the centrifugal machine, and then inoculating the layer of cream and the deposit thus obtained into guinea-pigs, three out of the forty-four samples were found to contain tubercle bacilli, for three of the animals thus treated succumbed to tuberculous infection. Dr. Massone points out how important it is that all tests of milk for tubercle bacilli should be made by direct inoculations into animals, as no trust can be placed on microscopic evidence as to the freedom of milk from this species of infection. In conclusion the author emphasises once more the inconsistency which attends the severe restrictions imposed in many places upon the sale of meat obtained from tuberculous animals, whilst no attention is paid, or public importance attached, to the prevention of milk being distributed infected with these noxious germs. In the former case, owing to the meat being cooked before use, less danger attaches to its consumption, whilst the unfortunate custom which prevails of drinking milk in its raw unsterilised condition, renders the use of contaminated milk a greater menace even to the health of the community than the distribution of tuberculous meat.

EVERYTHING concerning the Island of Jamaica, from its discovery by Columbus in 1494 to the present time, will be found in the admirable "Handbook of Jamaica," published by authority (Mr. Edward Stanford is the London agent), and prepared by Mr. S. P. Musson and Mr. T. L. Roxburgh. At the end of the chronological history of the island, reference is made to the publication of Prof. Williams' report on the cattle disease in Jamaica. The conclusion arrived at is that the disease "is a chronic form of Texan fever conveyed from place to place and transmitted from one animal to another through the intervention of the Tick. The infection is conveyed by the progeny of Ticks which have matured on infected cattle, and is inoculated by them directly into the blood of susceptible cattle." Remedies for the destruction of the Tick are suggested in the report.

THE New Zealand Institute has just commenced to publish, in quarto form, a series of reproductions of photographs of the remaining monuments of Maori skill and art, with short descriptions of the specimens figured. The author of this important descriptive work, Mr. Augustus Hamilton, Registrar of the University of Otago, has, with his camera, visited many outlying parts of Maoriland with great enterprise and success. The pictures obtained by him have been photographically reproduced in extremely fine tone; so that the complete collection will preserve for the ages the characteristics of the ornamentation of the Maoris, when the "devouring tooth of time" has obliterated the originals. It is hardly necessary to explain to readers of NATURE that a publication of this character is of the highest value. The first part, which has just been issued, describes the canoes of the Maoris and the carvings upon them; this, with four other parts illustrating the dwellings, weapons, dress and decoration, and social life, will complete a volume. It is expected that Part ii. will be ready next August.

IN the Catalogue of the Vienna Exchange Office for Cryptogamic Plants, conducted by Herr J. Brunnthaler, Igelgasse 11, Vienna, iv/2, are offered for exchange or sale some 600 Mosses, 140 Hepatics, 940 Fungi, 580 Lichens, 690 Algæ, and 48 microscope slides. The value attached to every specimen is expressed in the units (twentieths of a shilling) adopted for convenience of exchange, the valuation depending on the quality and rarity of the specimen. Numerous regulations are given as to the condition, preparation, and labelling of specimens sent for exchange to the Office. Lists of such specimens as can be supplied for exchange must reach the office by September 15. From the parcels subsequently sent in a deduction of 25 per cent. of the

total value is made for the benefit of the Office. The valuation of European plants is settled by the director, who is willing to receive Vascular Cryptogams and Bacteria in addition to the groups mentioned above. Descriptions of some new species of Fungi are published in the current Catalogue.

DR. RICHARD HERTWIG'S "Lehrbuch der Zoologie," which was reviewed in NATURE in June 1893 (vol. xlviii. p. 173), has reached a fourth edition. The section on the Sporozoa has been revised, and some additions have been made in the section on the Vertebrates. The work is published by Gustav Fischer, Jena.—Messrs. Blackie and Son have published what is nominally a fourth edition of Mr. Jerome Harrison's "Text-Book of Geology"; but the additions and changes are so numerous that the work is practically a new one, the type having been entirely re-set. The book is "intended as an introduction to the study of rocks and their contents," and it will, we believe, be the means of adding to the number of out-door students of geology, notwithstanding the fact that it belongs to the class of examinational text-books. The text is clearly printed, and the illustrations are numerous and generally instructive.—Messrs. J. and A. Churchill have published the second edition of "A Manual of Botany," by Prof. J. Reynolds Green, F.R.S. Very few changes have been made in the work.

WE have upon our table a number of important geological memoirs and reports lately published. Geologists will be glad to have their attention drawn to these publications. From the Geological Survey of India we have received the first memoir of a new series (Series xvi.) of the Palæontologia Indica, intended to comprise a description of the fossils found in Baluchistan. The first part of the new series comprises the Jurassic Fauna of Baluchistan, and in the present memoir, Dr. Fritz Noetling deals with the fauna of the Kellaways of Mazár Drik. The geology of the Bellary district, Madras Presidency, is described by Mr. R. Bruce Foot in vol. xxv. of the memoirs of the Survey; and the geology of Hazara and the Black Mountain is dealt with by Mr. C. S. Middlemiss in vol. xxvi. of the same memoirs. Both of these papers are full of details referring to the geology of the district surveyed by the authors, and each of them throws light upon problems of more than local interest.

A REPORT on explorations in the Labrador Peninsula along the East Main, Koksoak, Hamilton, Manicuagan, and portions of other rivers, made by Mr. A. P. Low in 1892–95, has been published by the Geological Survey of Canada (Part i., Annual Report, vol. viii.). This is an interesting account of exploration, containing much new information in regard to the geology and natural history of the Labrador Peninsula. A concise and readable summary of the observations made, and the conclusions reached from them, takes up one part of the report, and the remainder consists of detailed descriptions of the routes, the rocks noted, and other observations for the use of future explorers in the region traversed. Lists and notes on the fauna and flora of Labrador, and a meteorological record are printed as appendices to the report. We have also received Part R of the same annual report (vol. viii.) containing an account of the work carried out in the Laboratory of the Survey during 1896, by Dr. G. C. Hoffmann. In this report reference is made to several interesting and, in some instances, valuable minerals, not before known in Canada. Two other recent publications of the Geological Survey of Canada are: "Report on the Country between Athabasca Lake and Churchill River," by Mr. J. Burr Tyrrell, assisted by Mr. D. B. Dowling; and "Palæozoic Fossils," by Mr. J. F. Whiteaves. The latter paper is the third part of the third volume on Palæozoic Fossils now in course of publication by the Canadian Survey.

THE twenty-second and twenty-third annual reports of the Geological and Natural History Survey of Minnesota, referring to the work done during 1893–94, have been received from the State Geologist, Mr. N. H. Winchell. The latter report contains a paper by Mr. Winchell on "The Origin of the Archean Greenstones." The paper is a critical examination of a paper by Dr. G. H. Williams, tending to the conclusion that the greenstones, as a body, may be referred to dynamic metamorphism of massive eruptive rocks. Mr. Winchell believes "that the great bulk of the 'greenstones' as an Archean terrane, ought to be classified as pyro-clastic, *i.e.* that they originated from eruptive agencies, as tuff and all kinds of volcanic débris, sometimes very coarse, and were distributed and somewhat stratified by the waters of the ocean into which the materials fell."

THE additions to the Zoological Society's Gardens during the past week include two Vervet Monkeys (*Cercopithecus lalandii*, ♂ ♀), two Crested Porcupines (*Hystrix cristata*) from South Africa, presented by Mr. J. E. Matcham; a Brown Bear (*Ursus arctos*), European, presented by Mr. William Forbes; a Black-necked Grackle (*Gracupica nigricollis*) from China, presented by Mr. B. H. Jones; a Ring-necked Parrakeet (*Palæornis torquata*) from India, presented by Mrs. Doyne; five Common Chameleons (*Chamæleon vulgaris*) from Egypt, presented by Dixon Bey; a Ring-tailed Lemur (*Lemur catta*), two Black-headed Lemurs (*Lemur brunneus*) from Madagascar, two Korin Gazelles (*Gazella rufifrons*, ♂ ♀) from Senegal, a Fennec Fox (*Canis cerdo*), six Egyptian Foxes (*Canis niloticus*), a Pale Genet (*Genetta senegalensis*), three Leith's Tortoises (*Testudo leithi*) from Egypt, a Harnessed Antelope (*Tragelaphus scriptus*, ♀) from West Africa, deposited; a Californian Sea Lion (*Otaria californiana*, ♀) from the North Pacific Ocean, two Ostriches (*Struthio camelus*, ♂ ♀) from Africa, purchased; a Long-legged Jackal (*Canis variegatus*) from North-east Africa, three North African Jackals (*Canis anthus*), a Striped Hyæna (*Hyæna striata*) from Egypt, received in exchange; an Eland (*Orias canna*, ♂), a Patagonian Cavy (*Dolichotis patachonica*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE LATITUDE OF THE ROYAL CATANIA OBSERVATORY.—The Italian Royal Geodetical Commission have just published a detailed account of the determination of the latitude of the Royal Astronomical Observatory of Catania by Dr. T. Zona, of the Royal Observatory of Palermo. All the observations were made during the year 1894, and the method adopted was that of Talcott. The pairs of stars used amounted to twenty-three in number, and their places were obtained from each of the three separate catalogues, viz. Respighi, Bradley-Auwers, and the British Association Ten-Year.

Dr. Zona has not attempted to amalgamate the positions of each star as given by the three separate catalogues, by using a mean value, but has preferred to determine three values for the latitude, basing each on the separate catalogue star positions for the pair employed.

In this way computation has given for the final values of the latitude, based on the star positions of each catalogue, the following results:—

Respighi	$37° 30' 13''.239 \pm 0''.115$
Bradley-Auwers	13.216 ± 0.132
Ten-Year	13.302 ± 0.108

The final value adopted for the latitude of the transit instrument of the observatory was

$$37° 30' 13''.254 \pm 0''.068.$$

PHYSICAL AND MICROMETRICAL OBSERVATIONS OF VENUS.—The amount of detail visible on the disc of Venus is not so very prominent, according to the observations recently recorded by Prof. Barnard (*Astrophysical Journal*, vol. v. No. 5). Those observers who up to the present time have only made out dusky

patches on her surface will feel satisfied that this well-known observer has not yet detected such tracings as have been put before us by Lowell. Venus was frequently observed by him with the 12-inch refractor of the Mount Hamilton Observatory during the years 1888–95, but as he says he "never could (with but one exception) satisfactorily see the markings. Vague indefinite spots were often visible, but it was not possible to see them well enough to identify them for rotational purposes." With these facts before us, it is not then surprising that the observed periods of the planet should vary from twenty-three or twenty-four hours to 225 days. The exceptional case of good seeing mentioned above was "when the air was thick with smoke and dust. . . . I was struck with the remarkably perfect definition. There was not the slightest tremor. The markings on the surface of the planet were distinctly seen, though they were difficult and very delicate." The drawing which accompanies Prof. Barnard's description shows the crescent of Venus with four large hazy patches very much foreshortened in their position near the limb.

To continue his series of measurements of the diameters of all the planets with the 36-inch, Prof. Barnard, in May, June and July of 1895, undertook that of Venus. The mean of all his measures reduced to unit distance gave a diameter of 17″·397, corresponding to an actual diameter of 7826 miles.

This value seems to be very satisfactory when compared with the mean of all previous determinations, as will be seen in the following table.

Hartwig	... Breslau heliometer	17″·67
,,	... Reduction of Oxford measures ...	17·582
,,	... Double image observations by Kaiser	17·409
,,	... Nine measures in Bahia-Blanca ...	17·406
Peter	... Two measures in Bahia-Blanca ...	17·216
Küstner	... Two measures in Punta Arenas ...	17·312
Auwers	... Measures during transit	16·801
Ambronn	... Göttingen heliometer	17·711
	Mean	17·389
Barnard	... 36-inch Lick refractor...	17·397

NEBULÆ UNRECORDED IN CATALOGUES.—In the current number of the *Observatory*, Dr. Roberts gives a list of several nebulæ which have not found a place in catalogues, but which have been recorded on the plates used in his photographic survey. These photographs were taken with his fine 20-inch reflector at Crowborough, and a comparison between these and the recorded places of nebulæ in the "New General Catalogue," and the "Index Catalogue," by Dr. Dreyer, has been fruitful of many discoveries. Of the seventeen new nebulæ, we extract the following description of the largest:—

Region of ℌI. 157 Trianguli, N.G.C. 672; Nova, R.A. 1h. 39m. 39s. N.P.D. 63° 22′·3.—It is nearly as large and prominent as ℌI. 157, and distant from centre to centre 8′ only; nucleus consists of six faint stellar condensations forming a straight line in the direction south, following to north preceding, and there are six or seven very faint condensations of nebulosity near the preceding margin; 15th mag. star on the north preceding margin, and a 16th mag. star at the south following end of the nucleus, 1896 November 29.

It is remarkable that this object should have escaped detection by the many keen-eyed observers who have examined the nebula ℌI. 157, which is only four minutes of arc distance from it; and it appears to me that we are justified by the evidence in inferring that this nebula has come into the state of visibility during the past half-century. Lord Rosse, in 1896, made several observations of the nebula adjoining, but does not refer to this one. It is remarkable also that the nuclei of the two nebulæ are straight lines of faint nebulous stars immersed in nebulosity, and they are so clearly depicted on the photograph that I think they should be visible to the eye by the aid of telescopic power.

Dr. Roberts finds further, by examining his negatives, that two classes of stars, which he terms "faint" and "small," attract notice. The former have small bright nuclei surrounded by nebulosity, and are quite distinct from the latter, which appear as small round spots without a nucleus. These, he states, would, if they were classified, come under the heading, "small circular nebulæ with small bright stellar nuclei."

HARVARD COLLEGE OBSERVATORY ZONE OBSERVATIONS.—Volume xxxvi. of the *Annals* of the Astronomical Observatory of Harvard College contains the journal of the zone observations of stars between 49° 50′ and 55° 10′ of North Declination. These observations were made with the meridian circle during the ten years 1875 to 1885 by Mr. William Rogers, under the direction of the successive directors Joseph Winlock and E. C. Pickering. The present volume completes the journal begun in volume xxxv., and in this review all doubtful cases have been re-examined.

THE ROYAL OBSERVATORY, GREENWICH.

THE Astronomer Royal presented his annual report on Saturday last to the Board of Visitors of the Royal Observatory, Greenwich. Among the numerous guests were many astronomers and men of science, who inspected the buildings and instruments, especially those which have been erected since the visitation last year, namely, the Thompson equatorial and the new altazimuth. The following extracts from the report contain a brief *résumé* of the year's work.

Buildings.

The building of the north wing and central dome of the Physical Observatory was finished in September 1896, with the exception of the vane on the central dome, which was completed last March.

An observing floor and gallery have quite recently been fitted up in the dome to facilitate work with the new Thompson equatorial, now mounted there. The completion of the Physical Observatory by the building of the east and west wings has been further delayed, though provision was made for commencing the work in the last financial year.

The Transit Circle.

With regard to this instrument, it has been found that the apparent correction for discordance between the nadir observations and stars observed by reflexion has been gradually increasing yearly, the difference for the present year being −0″·44, the greatest negative value recorded since 1888.

The increase in this discordance in 1896, following on the systematically negative values since 1891, led to a re-examination of the screws of the microscope-micrometers, of the screw of the telescope-micrometer, and of the errors of those divisions of the circle which are used in observations of the nadir, with a view to the discovery of the source of this discordance.

The microscope-micrometers showed signs of wear, but the reversal of three of the screws has successfully eliminated the effect of wear from the mean of the six microscopes.

The New Altazimuth.

This instrument was erected in May 1896, but it was not practicable to make observations with it till the completion of the observing floor in September. It was then found that there were serious discordances in the readings of the circles under the different microscopes, depending on the direction in which the instrument was last turned. Experiments indicated flexure in the axis, which has now been corrected by stiffening the axis by means of a strong diaphragm of special form fitted in the central part of the axis. The friction-rollers for taking the weight of the instrument have also been modified, the position being changed to bring them close to the pivots, and a system of levers has been substituted for springs. These changes reduced the discordances greatly in amount. Quite recently Mr. Simms has discovered a cause of error, arising from a tendency in the pivots to act as a screw, a longitudinal force being thus introduced, its direction depending on the direction in which the telescope is turned. This force had the effect of slightly moving the iron standards carrying the bearings and the microscopes, thus changing the position of the microscopes relatively to the graduated circles. This action of the pivots was found to arise from the method adopted in grinding them of giving a helical twist to the grinder, and it was cured by a few circular turns of the same tool.

The Thompson Equatorial.

This new instrument, presented by Sir Henry Thompson, forms a handsome addition to the Observatory, and it has been mounted in the Physical Observatory under the Lassell Dome. Its erection there was commenced early in November, but it was not ready for use till April, and there are still certain accessories which have to be supplied. The adjustment of the polar axis and of the 26-inch object-glass were at once taken in

hand, and the former was soon satisfactorily effected. For the adjustment of the object-glass a number of photographs have been taken inside and outside of the focus, the separation between the lenses being varied with a view to the correction of the small outstanding aberration and coma. Some photographs of the moon and of double stars have been taken, an enlarging camera with a Dallmeyer concave magnifier being applied to the telescope in some cases to give a magnified image. This equatorial carries not only the 26-inch photographic telescope with the 12¾-inch Merz guiding telescope and the Thompson 9-inch photoheliograph, but also a Cassegrain reflecting telescope of 30 inches aperture with the 6-inch Hodgson telescope as guider in place of the counterpoise at the other end of the declination axis. It thus provides a very powerful combination of telescopes specially adapted to photographic work of various kinds, and special arrangements in the instrument and observing room have been necessary to meet the varied requirements. The instrument has now been got into good working order, and is very satisfactory as regards the mechanical arrangements. The photographic spectroscope will be used in connection with the Cassegrain reflector mounted firmly at the back of the cell of the mirror, a diagonal prism being used to reflect the rays into the collimator.

The 28-inch Refractor.

This instrument was in constant use for micrometric measurements from 1896 May 11, to 1897 January 11. On January 12 the crown lens was reversed, and the instrument used for photography till April 23, except on the occasion of Prof. Barnard's visit to the Observatory, when the lens was replaced in the visual position. Besides several micrometric observations, 195 double stars were measured during the year ending May 10. The distance and position-angle of the satellite of Neptune were measured on four nights, and the equatorial and polar diameters on two nights. The equatorial and polar diameters of Mars were measured on seven nights. With the crown lens in the reversed position, a number of photographs was taken in and out of focus for the better adjustment of the separation of the lenses and the tilt.

The Astrophysical Equatorial.

The following statement shows the progress made with the photo-mapping of the heavens :—

	For the Chart (exposure 40m.).		For the Catalogue (exposures 6m., 3m. and 20s.).
Number of photographs taken	175	...	139
,, successful plates ...	135	...	110
,, fields photographed successfully...	133	...	98
Total number of successful fields reported 1896, May 10 ...	490	...	732
Number of photographs, previously considered successful, rejected during year ...	72	...	16
Total number of successful fields obtained to 1897 May 10 ...	551	...	814
Number still to be taken ...	598	...	335

Of the fields still required 197 are within 10° of the Pole, and no photographs of this part of the sky have yet been taken, the work being purposely deferred till near the epoch 1900.

Spectroscopic and Heliographic Observations.

Photographs of the sun were taken on 222 days, and of these 471 have been selected for preservation, besides twelve photographs with double images of the sun for determination of zero of position-angle.

For the preceding year Greenwich photographs were selected for measurement on 206 days, and photographs from the Solar Physics Committee (filling up the gaps in the series) on 154 days, making a total of 360 days out of 366 on which photographs are available.

The spot activity of the sun has continued on the whole to decline since the date of the last Report, but has undergone two remarkable cases of temporary revival; the one in September 1896, when the longest connected group ever photographed at Greenwich was observed, and the other at the commencement of the present year. On the other hand, the sun was seen to be free from spots on six days in the year ending 1897 May 10.

Magnetic Observations.

The variations of magnetic declination, horizontal force and vertical force, and of earth currents have been registered photographically, and acccompanying eye observations of absolute declination, horizontal force and dip have been made as in former years.

The principal results for the magnetic elements for 1896 are as follows :—

Mean declination ...	16° 56'·5 West.
Mean horizontal force	3·9834 (in British units). 1·8367 (in metric units).
Mean dip	67° 8'·5 (by 9-inch needles). 67° 9'·3 (by 6-inch needles). 67° 10'·0 (by 3-inch needles).

These results are to a certain extent affected by the iron in the new Physical Observatory, and in the new Altazimuth Pavilion.

The selection of the site for the new Magnetic Pavilion required much consideration and necessitated observations at a number of stations in Greenwich Park. As the result of the survey it was decided to abandon a site which had been provisionally selected at a distance of about 250 feet to the east of the reservoir, and to choose another at a considerably greater distance both from the reservoir and the Observatory.

Meteorological Observations.

The mean temperature of the year 1896 was 50°·1, being 0°·7 above the average for the fifty years 1841–1890.

During the twelve months ending 1897 April 30, the highest daily temperature in the shade recorded on the open stand was 91°·1 on July 14. The highest reading recorded in the Stevenson screen was 87°·6. Under the same conditions of exposure on the open stand there have been twenty-six instances of temperatures exceeding 90° recorded in the preceding fifty-five years, the highest having been 97°·1 on 1881 July 15. The temperature rose twice above 90° in 1896, and seventeen times above 80°. The monthly mean temperatures for June, July, February and March were respectively above the corresponding averages by 4°·0, 2°·8, 3°·5 and 3°·3 ; and the means for August, October, November and January were in defect by 2°·5, 3°·5, 2°·7 and 3°·1. The mean temperature for the twelve months 1896 May to 1897 April was 49°·7, being 0°·2 above the fifty years' average.

In the winter months of 1896–1897 there were forty-two days on which the temperature of the air fell to the freezing-point, or below ; sixteen of these days occurring in January, and eleven in December. The lowest winter temperature was 23°·8 on 1897 January 18, as compared with 24°·3 in the preceding winter.

The number of hours of bright sunshine recorded during the twelve months ending 1897 April 30 by the Campbell-Stokes instrument (with the old ball up to December 31, and with the new ball after), was 1152 out of the 4454 hours during which the sun was above the horizon, so that the mean proportion of sunshine for the year was 0·259, constant sunshine being represented by 1. This amount is probably too small for reasons stated in the report.

The rainfall for the year ending 1897 April 30 was 26·83 inches, being 2·29 inches above the fifty years' average. The number of rainy days in the twelve months was 178.

Personal Establishment.

In the last Report mention was made regarding the reorganisation of the staff. The arrangement now adopted is that Mr. Dyson and Mr. Cowell have the general superintendence of all the work of the Observatory, Mr. Dyson taking special charge of the astronomical department, and Mr. Cowell of the astrophysical department, in which is included the magnetic and meteorological branch. Mr. Maunder is charged with the heliographic photography and reductions. Mr. Lewis has charge of the time-signals and chronometers, and of the 28-inch equatorial. Mr. Thackeray superintends the miscellaneous astronomical computations and meridian zenith-distance reductions. Mr. Hollis has charge of the photographic mapping of the heavens, the measurement of the plates, and the computations for the astrographic catalogue. Mr. Crommelin undertakes the altazimuth and Sheepshanks equatorial reductions, and Mr. Bryant the transit-reductions and time-determinations. In the magnetic and meteorological branch, Mr. Nash has the charge of the whole of the work.

INSECTS AFFECTING DOMESTIC ANIMALS.[1]

THIS work is one of the most recent of the many valuable publications on economic entomology for which we are indebted to the Department of Agriculture of the United States, and is a well-printed and well-illustrated volume of about 300 pages, giving, firstly, an enormous amount of useful information on the histories and means of prevention of insects injurious to wild and domesticated animals, and also to man. Following on this are about sixty pages devoted to the wingless parasites, classed scientifically in the sub-order *Mallophaga* more shortly here as "biting lice"; and a further division, of about twenty-five pages, gives under the heading of *Arachnida* some of the most important representatives of the "mites, ticks, scab insects, mange insects, &c."

The value of the book is much enhanced by the excellent supply given of explanatory adjuncts, including in these a very full table of contents, with number of page bracketed to name of each insect or parasite; also an introduction dealing mainly with points of entomological classification, distribution of the pests, as to the divisions of mammals, birds, &c., affected by them, and "Effects of Parasites on the Host, &c."

The body of the book is followed by "A List of Parasites according to Hosts"; several pages with titles of works more especially bearing on the infestations previously entered on, together with the names of their authors, and a good index completes the useful volume.

In the "letter of transmittal" of the work to the U.S. Secretary of Agriculture, it is noted by Dr. L. O. Howard, Entomologist to the Department, that "the Report will form an excellent text-book of the subject, and is a work which in the opinion of the writer should be in the hands of all stock raisers." This, of course, refers primarily to stock raisers of the United States; but even on our side the Atlantic, from the plainness of the descriptions, both of infestations and remedies, the information will be of much practical use, and also as a scientific as well as practical manual should be in the hands of all our economic entomologists.

The book may be considered as in some degree a legacy, or posthumous contribution by the late Prof. Riley to the work of economic entomology, which he had so much at heart, as we are told in the "Prefatory Note" that the report was originally planned in 1885 as a conjoint work with Dr. C. V. Riley, and it is matter of congratulation that the plans have fallen in their completion into such very well-qualified hands as those of Prof. Osborn.

The accounts of the infestations consist, for the most part, of plainly-worded descriptions of the insects (suitable for general

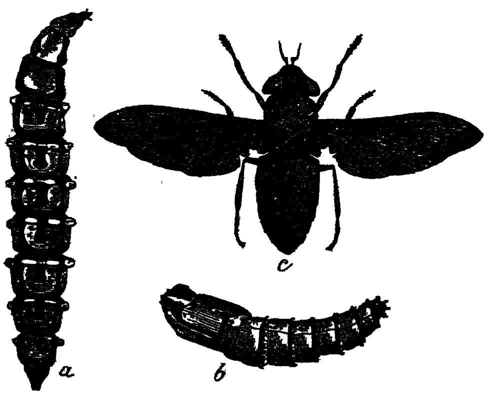


FIG. 1.—*T. atratus*.

use), with notes of habits, distribution, or other points of interest, and measures of prevention and remedy. The figures are clear and good, and that at p. 61, of "The Black Gad Fly" (*Tabanus atratus*), after Prof. Riley, gives a good example of method of representation of the insect in all its stages (Fig. 1). The figure at p. 118, of a cow's horn with the base covered with the clustering masses of the "horn fly" (*Hæmatobia serrata*), gives a guide to the appearance of the infestation *in situ*, unmistakable by the most superficial observer (Fig. 2). A single extract from

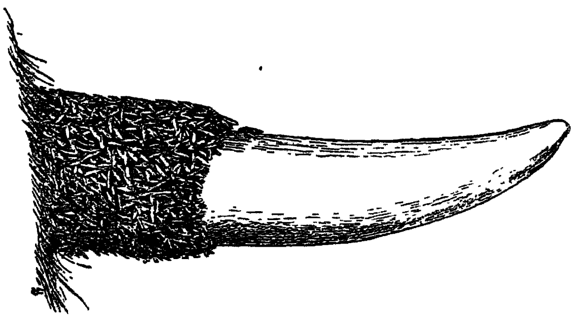

FIG. 2.—Infested cow's horn.

the table of contents may serve as a specimen of the completeness with which the work is given.

"Family SIMULIIDÆ (black flies, buffalo gnats). Losses from buffalo gnats (p. 32)—Life-history and habits (p. 33)—Preventives (p. 36)—Remedies for the bites (p. 37)—Natural enemies of buffalo gnats (p. 38)—Descriptions of species with notes on their habits (p. 38)—The Columbacz midge (p. 38)—*Simulium ornatum* (p. 39)—The black fly (p. 40)—The Southern buffalo gnat (p. 41)—The Turkey gnat (p. 52)—The Western buffalo gnat (p. 55)—*Simulium piscicidium* (p. 56)—*Simulium canescens* (p. 57)—*Simulium rivulara* (p. 57—*Simulium* sp., in Brazil (p. 57)—*Simulium venustum* (p. 57)—*Simulium* sp., near Washington (p. 58)—*Simulium pictipes* (p. 58)."

E. A. O.

[1] "Insects affecting Domestic Animals: an Account of the Species of Importance in North America." By Herbert Osborn, Professor of Zoology and Entomology, Iowa Agricultural College, Ames, Iowa. Bulletin No. 5, New Series, U.S. Department of Agriculture, Div. of Entomology. (Washington: Government Printing Office, 1896.)

THE ENGWURRA, OR FIRE CEREMONY OF CERTAIN CENTRAL AUSTRALIAN TRIBES.[1]

AMONGST certain tribes inhabiting the centre of Australia, the last of the initiation ceremonies through which every man must pass before he is fully admitted to all the sacred mysteries of the tribe, takes the form of a series of what may be called ordeals by fire. Some such ceremony is known to us to exist amongst the Urabunna tribe, in the neighbourhood of Lake Eyre; in the Arunta tribe, which extends across the centre of the continent to about seventy miles north of the Macdonnell Range; and also in the Ilparra and Warramunga tribes, who extend at least two hundred miles still further to the north.

We cannot fully translate the term Engwurra, or Urrumpulla, by which the rite is known in certain parts, but each of them is formed in part of the word *ūrra*, which means fire. The Arunta natives say that the ceremony has the effect of strengthening all those who pass through it. It imparts courage and wisdom, makes the men more kindly-natured, and less apt to quarrel; in short, it makes them *ertwa mūrra oknirra*, words which respectively mean, in the Arunta tongue, "men, good, very, or great."

Evidently the main objects of it are, firstly, to bring the younger men under the control of the elders, whose commands they have implicitly to obey; secondly, to teach them habits of self-restraint and hardihood; and thirdly, to show to the younger men who have arrived at mature age, the sacred secrets of the tribe, especially those which are associated with the totems.

The Engwurra is the fourth of the initiatory rites through which every Arunta native has to pass. Of two of the three earlier ones the details have already been described by one of us,[2] and, stated briefly, the ceremonies are as follows. At the age of about ten or twelve the boys are taken to a spot close to the main camp, where the men and women assemble. Whilst

[1] The paper, of which this is an outline, was read before the Royal Society of Victoria, in April, by Prof. Baldwin Spencer and F. J. Gillen, Sub-Protector of Aborigines, Alice Springs, South Australia.

[2] F. J. Gillen, in "Report on the Work of the Horn Exped. to Cent. Aust." Part iv., "Anthropology," p. 169. Plates 16, 17, 18.

the women dance round, the men toss the boys in the air and catch them as they fall.

This over, they are painted on the back and chest with straight or curved bands outlined by red or yellow ochre lines, the painting being done by a man who stands in the relationship to the boy of brother to a woman whom it will afterwards be lawful for him to take as wife. The boy is told that this ceremony will promote his growth, and that the time has now come when he must no longer play with, and live at the camp of, the women and children, but must go to that of the unmarried men, and live with them. He begins to accompany the men in their hunting expeditions, listens to their talks around the camp fire at night, and looks forward to the time when he shall be admitted to the privilege of manhood.

Some years elapse before the second ceremony is performed. When he arrives at puberty, or possibly not till some time later, the rite of circumcision is practised; and a short time after this, there follows the third rite—that of sub-incision. When he has passed through these three ceremonies, the native is admitted to the ranks of the men; he may wear a hair girdle round his waist, tie his hair back with the forehead-band, and may take a wife.

The different periods of his life are indicated by different terms. When a mere child, he is Amba-querka; after having been thrown up, he is Ulpmerka; after circumcision, he is Arrakurta; after sub-incision, he is Ertwa-kurka; and finally, when he has passed through the Engwurra, he becomes an Urliara.

The Engwurra ceremony, which the authors witnessed, was held amongst the Macdonnell Ranges, in the vicinity of Alice Springs telegraph station on the overland telegraph line between Adelaide and Port Darwin. Of this station one of the authors is officer in charge; and his long acquaintance with the natives, as well as the fact that he is Sub-Protector of the Aborigines, has given him special facilities for gaining their confidence.

The ceremony lasted four months, commencing in September 1896, and ending in January 1897; and during this period the authors spent the greater part of the time in the native camp, being allowed to witness everything which took place—being, in fact, regarded as members of the tribe.

The spot chosen for the ceremony was a level stretch of ground, hemmed in on one side by a range of rugged quartzite, and on the other by the River Todd, which, like all other Central Australian rivers, is, except at rare intervals, a dry tract of sand bordered by steep banks on which grows a fringe of gum-trees and low scrub. This level flat formed the Mirra Engwurra, or Engwurra Camp. The women's camp was out of sight on the other side of the river; for, needless to say, the women and uninitiated were not allowed to go anywhere near to the sacred ground.

The natives are summoned to the Engwurra by messengers sent out by the old man who presides at the ceremony. There may be one or more messengers, and each carries one or two of the sacred sticks or Churinga wrapped up from sight in emu feathers, the Churinga being of the nature of the objects commonly called bull-roarers. The messenger who summons to the Engwurra is called *Ilchinkinja*, the word being a compound of *ilcha*, hand, and *inkinja*, to lift up, and may be translated by the term "the beckoning hand." The significance of the Churinga will be seen shortly; meanwhile it may be said that in their natural state no native dare disobey such a summons, through fear of the harmful consequences which would befall him if he did so.

Representatives of the different local groups of the Arunta tribe assembled early in September, each group bringing with it stores of its sacred Churinga, which were under the careful charge of the elder men.

Before going further, it is necessary to allude briefly to the organisation of the tribe. Its division into exogamously intermarrying phratries or classes has been already clearly shown by Messrs. Howitt and Fison, and later by Messrs. Gillen and Stirling. There is little doubt but that originally there were two main phratries, each of which became divided again into two, whilst at the present day the division has been, or rather is now being, carried still further, with the result that instead of four, we have eight sub-phratries. This division into eight exists in reality throughout the tribe; but it is only amongst the northern groups that there are separate names for each of them, and it will be simpler here to deal with the four which are found throughout the tribe. The names of these four are Panunga, Bultharra, Purula and Kumarra. One moiety of the tribe consists of the first two, the other of the second two. The marriage arrangements are as follows:—

Bultharra (male)	marries	Kumarra,	children are	Panunga.
Panunga	,,	Purula,	,,	Bultharra.
Purula	,,	Panunga,	,,	Kumarra.
Kumarra	,,	Bultharra,	,,	Purula.

Every Bultharra man, for example, must marry a Kumarra woman, that is, one who comes from the moiety of the tribe to which he does not belong, and their children, go into the man's moiety, but into the sub-phratry to which he did not belong. At the same time the Kumarra women are divided into two sets, owing to the social organisation—details of which will subsequently be published by the authors—and these two sets stand respectively to each individual Bultharra man in the relationship of what is called Unawa and Unkulla, and it is only the former who are eligible to him as wives. In just the same way the Bultharra men are divided into two sets, who stand respectively to any Kumarra woman in the relationship of Unawa, whom she may marry, and Unkulla, whom she may not.

There can be no doubt whatever about the fact that the Panunga and Bultharra form one moiety, and the Kumarra and Purula another. This is shown in various ways, and when large numbers of the natives are gathered together at such a ceremony as the Engwurra, it stands out most clearly. Not only are there two main camps on the Engwurra ground, at one of which the Panunga and Bultharra gather, and at the other the Purula and Kumarra, but the sacred Churinga are deposited in two separate spots, those of the Panunga and Bultharra being placed, during the Engwurra which the authors witnessed, on a platform erected in a Mulga tree on the hill-side, overlooking at one end the ceremony ground, whilst those of the Kumarra and Purula were placed on a small platform at the opposite end.

As soon as the natives had begun to assemble, the Alice Springs blacks, in whose locality the ceremony was to be performed, opened the proceedings by performing two corrobborees, or ordinary dancing festivals, which occupied the evenings of the first three weeks, and at which, as they are not sacred, the women are allowed to be present, and to take part.

Before these were finished, the old man presiding over the Engwurra went to the chosen ground, and there raised a small mound of earth about forty feet long, one foot high, and two feet across, planting all along it small boughs of Eucalyptus. This mound is called the Parra, and apparently represents a tract of country. When this was done, the older men, who had already passed through the ceremony, and had thus become Urliara, together with the younger men, about forty in number, and varying in age from twenty to thirty-five, or even forty, who were to be made Urliara, spent the whole time during the ensuing two and a half months in the performance of sacred ceremonies on the Engwurra ground. Every day a certain number of young men are sent out to hunt for game, but from this time forward until the end of the whole ceremony they are not supposed to go near the women's camps. They must sleep at night on the Engwurra ground, and are completely under the control of the older men, whose orders they must implicitly obey.

The sacred[1] ceremonies, of which the authors witnessed the performance of about sixty, were all concerned with the numerous totems into which the members of the tribe are divided, and the special object of the authors was to gain an insight into the totemic system, and in connection with this to arrive, if possible, at a correct knowledge of the significance of the Churinga. These Churinga, or sacred sticks and stones,[2] are the most valuable possession of the Arunta natives, and throughout the tribe they are stored in considerable numbers in special hiding-places, the exact locality of which is only supposed to be known to the older men of each local group in whose district they are preserved. The whole tribe is divided up into a large number of such local groups, who reside in and are regarded as the proprietors of a definite tract of land, and each of the latter is especially associated with the name of some object, which is usually that of an animal or plant, and is, in fact, the totem of

[1] The term sacred is used to distinguish them from the ordinary ones, such as the dancing festivals, commonly called corrobborees, which any one, women and children included, may witness, whilst the sacred ones may only be seen by initiated men.

[2] Remarks upon and drawings of some of these will be found in the work by Messrs. Gillen and Stirling, previously alluded to. Therein Mr. Gillen supplied the information that they were symbolic of the totems, which may be modified now by saying that each Churinga is symbolic of an individual belonging to a particular totem.

the majority of individuals who occupy that particular area. The whole country occupied by the Arunta—and the same is true of other tribes of which the authors have information—is divided up into a large number of parts, each comprising what the natives call an *Oknannikilla*, which may be described as a local totem centre. There are, for example, certain areas forming wild cat oknannikillas, others emu, kangaroo, mulga, frog, and so on, the exact position of which is known to the natives.

If, on the other hand, we examine the Urabunna tribe, which adjoins the Arunta on the south, we see clearly a fundamental difference in regard to the totemic system. The Urabunna are divided into two phratries, viz. Matthurrie and Kirarawa, and each of these again into certain totems, the same totem not occurring in both phratries. The organisation of the tribe is such that a Matthurrie man must marry a Kirarawa woman, and not only this, but there is the further restriction that a man of one totem must marry a woman of another. Thus a Matthurrie cricket man must marry a Kirarawa crow woman, and, as descent is counted through the mother, and not, as in the Arunta, through the father, the children are Kirarawa and crows.

In the Arunta it is quite different, and so far as the totems are concerned, at first sight most perplexing. The subphratry name is simple, every child of a Bultharra man and a Purula woman is a Panunga, and so forth, but there is no such orderly method in the totem names. The following actual examples of three, amongst many families investigated by the authors, are typical of what is found through the tribe.

In the first family the father is Hawk; wife No. 1, Bandicoot; daughter, Witchetty Grub; wife No. 2, Kangaroo; no children; wife No. 3, Lizard; two daughters, one Emu, the other Water.

In the second family the father is Witchetty Grub; wife No. 1, Lizard; no children; wife No. 2, Munyeru (grass seed); two daughters, one Lizard, the other Witchetty Grub.

In the third family the father is Eaglehawk; wife No. 1, Hakea flower; no children; wife No. 2, Hakea flower; three sons, respectively Witchetty Grub, Emu, Eaglehawk; two daughters, each Witchetty Grub.

Two things are clear, first, that the totems, as they now exist, have nothing to do with regulating marriage; and second, that the totems of the children do not of necessity follow either that of father or mother; they may be identical with either or both of them, or they may be entirely different.

It was whilst watching the ceremonies during the Engwurra, and questioning carefully the performers after each one was concluded, that the authors were able to gather information explaining this apparently perplexing system, and also to arrive at an understanding of the significance of the Churinga. The information derived is briefly as follows.

Each ceremony was connected with some particular totem and, further, with some special locality, and each one dealt with some particular ancestral individual or individuals. The traditions of the tribe refer back to a long past time called the Alcheringa (which means dream-times), when their ancestors were designated by the name of, usually, some animal or plant. Thus we have a group of individuals living in the Alcheringa, of whom it is difficult to say whether they were men-kangaroos or kangaroo-men, the identity of the human individual being sunk in that of the object with which he is associated, whose name he bears, and from whom he sprung. These kangaroo-men walked about the country now inhabited by the tribe, following a definite route and halting at certain places, the positions of which are well known to the natives by means of the traditions which have been handed down from generation to generation. In a similar way groups of Emu, Frog, Mulga, Wild Cat, and other individuals walked across the country.

Each one of these Alcheringa ancestors carried with him or her a number of sacred Churinga, and where they halted, there an oknannikilla or local totem centre was formed. At each spot, so says tradition, certain individuals went into the ground, and each became a Churinga, which is associated with the spirit part of the individual. Not only this, but at each such spot they deposited a large number of the Churinga which they carried, and with each one of which in the same way a spirit individual was associated.

Then the whole area now occupied by the tribe became, as it were, dotted over with a large number of local totem centres, and this idea of spirit individuals of definite totems, associated with Churinga and resident in certain spots, lies at the root of the present totemic system of the Arunta and other tribes of Central Australia.

Thus we have close to Alice Springs a large and important Witchetty Grub totem centre, and the following will serve as a typical example of how each man and woman gain a totem name. There were deposited in the Alcheringa, close by Alice Springs, a large number of Witchetty Churinga, each of course associated with a spirit individual. The latter can move about, and always carries with it its Churinga, and is supposed to frequent some special tree or stone, which is called its *Nanja* tree or stone. When a woman conceives, it is one of these spirit individuals who has entered her body, and therefore, quite irrespective of what the father or mother's totem may be, the child when born must of necessity belong to the spot at which it was conceived, or rather at which the mother believes that it was. Recently, for example, an Emu woman from another locality came on a visit to Alice Springs. There she conceived a child, but returned to her own Emu locality before that child was born. When born, that child was a Witchetty Grub—it must be, the natives say, because it entered the mother's body at Alice Springs, which is a Witchetty totem centre; it is, in fact, nothing more nor less than the reincarnation of an Alcheringa Witchetty Grub. Had it entered the mother within the limits of her own Emu locality, it would as inevitably have been born an Emu

Further, when the spirit-child enters the mother, it drops its Churinga. After it is born the mother tells the father exactly where it was conceived—that is, the spot where she first became aware that she had conceived a child—and the father and one or two other men go there, and either search until they find the Churinga, or if they do not find one, then they make one out of the mulga or other hard wood tree which lies nearest to the Nanja tree, carve on it the design of the child's totem, and hand it over for safe keeping to the head man of that locality, who places it in the sacred storehouse where all the Churinga of that totem centre are preserved. This Churinga becomes the Churinga Nanja of the child.

The meaning and importance of the Churinga may be gathered from the above sketch, from which many details, to be published later, are of necessity omitted.

It is during the Engwurra, and whilst the ceremonies concerned with the totems are being performed, that the old men of the tribe show the Churinga to the younger men, telling them to whom they have belonged and the traditions associated with them, and thus ensure the passing on of this knowledge from generation to generation; in fact, in ceremonies such as these we see the earliest beginnings of historical records.

Whilst the Engwurra is largely concerned with the performance of the sacred ceremonies, an equally important part is played by the fire ordeals from which the name is derived, and to which reference must now be briefly made. A full description of these, together with illustrations from photographs taken by the authors, will be published as soon as possible.

During the last month of the time occupied by the performance of the Engwurra the young men, who are being made Urliara, are taken out into the bush every day before sunrise, under the charge of certain elder men. There they have to remain all day hunting game, which must be brought in to the elder men, who stay in camp performing ceremonies. The young men are not supposed to eat much, and become poorer and poorer as the weeks pass by. Usually, but not always, they are brought back to the Engwurra ground by way of the women's camp. Just before sunset the women—Bultharra and Panunga in one spot, and Purula and Kumarra in another, some little distance apart—make a fire of bushes, and, standing behind this, move their hands as if inviting the young men, who are now called Illpongwurra, to approach. This they do, holding shields and boughs of a particular shrub over their heads. Then the lubras or women, carrying burning grass and boughs, run towards them, and throw the burning material over their heads. The men have to protect themselves with shields as well as they can, and after going to each fire they turn tail, followed by the women, who stop and run back again when they reach the bed of the river, on the other side of which lies the Engwurra ground, which they must not approach. Arrived at the latter, the young men lie down in a long row, each man having his head upon the Parra. Perfect silence is maintained, and here they must remain until the old men give them permission to arise. Each old man takes charge of four or five young men, who become what is called *apmūrra* to him and he to them, and no young man may speak to, or in the presence of, his apmūrra till all is over.

Within the last week of the ceremony the young men have to undergo another and more severe ordeal. In a secluded spot amongst the hills the old men, who have gone out in charge of them, make a large fire of logs. When these have burned down, and the red-hot ashes remain, green boughs of Eucalyptus are thrown on the fire, and on these the young men have to lie down in the heat and stifling smoke until they receive permission from the old men to get up.

Finally, on the last night the men all congregate around a sacred pole which has been erected close by the Parra, and here, all night long, the old men decorate the backs and chests of the younger men with designs, often very elaborate and distinctive, of the various totems. A man is not of necessity—in fact, very seldom is—painted with the design of his own totem. All night long the women remain awake and active in their camp across the river, where again they make two fires in shallow pits, but this time closely side by side.

Before sunrise the decorated men gather together at the base of the sacred pole, the head man of the ceremony breaks through the Parra mound, and across the opening thus formed the old men lead their charges, all walking in single file and holding one another's hands. In perfect silence the string of painted men pass from the Engwurra ground across the bed of the creek, and so on to the women's camp, where they form a group, and halt some fifty yards away from the women, who stand behind their fires, which are now giving off dense clouds of smoke from green gum boughs.

Then each old man takes the younger ones under his charge, and with them runs up to the fires. The Bultharra and Panunga men go to the fire made by the Purula and Kumarra women, and *vice versâ*, kneeling upon it while the women press them down with their hands upon the men's shoulders. When all have been upon the fires, the old men and the newly-made Urliara cross the river-bed again to the Engwurra ground, and sit around the sacred pole. The fire ceremonies are now complete, but as yet the younger men may not speak to their apmūrra, but must remain out in the bush. After a length of time, varying from two weeks to perhaps six months, each young man brings in a present of food called Chowarilya to his apmūrra man, when a sacred ceremony is performed, at the close of which the mouths of the old and young men who are present are touched either with the food brought in, or with some object which has been used in the ceremony, and the ban of silence is removed.

PROFESSOR NEWCOMB ON THE DISTANCES OF THE STARS.[1]

THE problem of the distances of the stars is of peculiar interest in connection with the Copernican system. The greatest objection to this system, which must have been more clearly seen by astronomers themselves than by any others, was found in the absence of any apparent parallax of the stars. If the earth performed such an immeasurable circle around the sun as Copernicus maintained, then, as it passed from side to side of its orbit, the stars outside the solar system must appear to have a corresponding motion in the other direction, and thus to swing back and forth as the earth moved in one and the other direction. The fact that not the slightest swing of that sort could be seen was, from the time of Ptolemy, the basis on which the doctrine of the earth's immobility rested. The difficulty was simply ignored by Copernicus and his immediate successors.

An indication of the extent to which the difficulty thus arising was felt is seen in the title of a book published by Horrebow, the Danish astronomer, some two centuries ago. This industrious observer, one of the first who used an instrument resembling our meridian transit of the present day, determined to see if he could find the parallax of the stars by observing the intervals at which a pair of stars in opposite quarters of the heavens crossed his meridian at opposite seasons of the year. When, as he thought, he had won success, he published his observations and conclusions under the title of "Copernicus Triumphans." But, alas! the keen criticism of his contemporaries showed that what he supposed to be a swing of the stars from season to season arose from a minute variation in the rate of his clock, due to the different temperatures to which it was exposed during the day and the night. The measurement of the distance even of the nearest stars evaded astronomical research, until Bessel and Struve arose in the early part of the present century.

On some aspects of the problem of the extent of the universe light is being thrown even now. Evidence is gradually accumulating which points to the probability that the successive orders of smaller and smaller stars, which our continually increasing telescopic power brings into view, are not situated at greater and greater distances, but that we actually see the boundary of our universe. This indication lends a peculiar interest to various questions growing out of the motions of the stars. Quite possibly the problem of these motions will be the great one of the future astronomer. Even now it suggests thoughts and questions of the most far-reaching character.

I have seldom felt a more delicious sense of repose than when crossing the ocean during the summer months I sought a place where I could lie alone on the deck, look up at the constellations, with *Lyra* near the zenith, and, while listening to the clank of the engine, try to calculate the hundreds of millions of years which would be required by our ship to reach the star α Lyræ if she could continue her course in that direction without ever stopping. It is a striking example of how easily we may fail to realise our knowledge when I say that I have thought many a time how deliciously one might pass those hundred millions of years in a journey to the star α Lyræ, without its occurring to me that we are actually making that very journey at a speed compared with which the motion of a steamship is slow indeed. Through every year, every hour, every minute, of human history from the first appearance of man on the earth, from the era of the builders of the Pyramids, through the times of Cæsar and Hannibal, through the period of every event that history records, not merely our earth, but the sun and the whole solar system with it, have been speeding their way towards the star of which I speak on a journey of which we know neither the beginning nor the end. During every clock-beat through which humanity has existed it has moved on this journey by an amount which we cannot specify more exactly than to say that it is probably between five and nine miles per second. We are at this moment thousands of miles nearer to α Lyræ than we were a few minutes ago when I began this discourse, and through every future moment, for untold thousands of years to come, the earth and all there is on it will be nearer to α Lyræ, or nearer to the place where that star now is, by hundreds of miles for every minute of time come and gone. When shall we get there? Probably in less than a million years, perhaps in half a million. We cannot tell exactly, but get there we must if the laws of nature and the laws of motion continue as they are. To attain to the stars was the seemingly vain wish of the philosopher, but the whole human race is, in a certain sense, realising this wish as rapidly as a speed of six or eight miles a second can bring it about.

I have called attention to this motion because it may, in the not distant future, afford the means of approximating to a solution of the problem already mentioned, that of the extent of the universe. Notwithstanding the success of astronomers during the present century in measuring the parallax of a number of stars, the most recent investigations show that there are very few, perhaps hardly more than a score of stars of which the parallax, and therefore the distance, has been determined with any approach to certainty. Many parallaxes, determined by observers about the middle of the century, have had to disappear before the powerful tests applied by measures with the heliometer; others have been greatly reduced, and the distances of the stars increased in proportion. So far as measurement goes, we can only say of the distances of all the stars, except the few whose parallaxes have been determined, that they are immeasurable. The radius of the earth's orbit, a line more than ninety millions of miles in length, not only vanishes from sight before we reach the distance of the great mass of stars, but becomes such a mere point that, when magnified by the powerful instruments of modern times, the most delicate appliances fail to make it measurable. Here the solar motion comes to our help. This motion, by which, as I have said, we are carried unceasingly through space, is made evident by a motion of most of the stars in the opposite direction, just as, passing through a country on a railway, we see the houses on the right and on the left being left behind us. It is clear enough that the apparent motion will be more rapid the nearer the object. We may, therefore, form some idea of the distance of the stars when we know the amount of the motion. It is found

[1] Extracted from an address given by Prof. Simon Newcomb at the dedication of the Flower Observatory, University of Pennsylvania, May 12.

that, in the great mass of stars of the sixth magnitude, the smallest visible to the naked eye, the motion is about three seconds per century. As a measure thus stated does not convey an accurate conception of magnitude to one not practiced in the subject, I would say that, in the heavens, to the ordinary eye, a pair of stars will appear single unless they are separated by a distance of 150 or 200 seconds. Let us then imagine ourselves looking at a star of the sixth magnitude, which is at rest while we are carried past it with the motion of six or eight miles per second which I have described. Mark its position in the heavens as we see it to-day; then let its position again be marked 5000 years hence. A good eye will just be able to perceive that there are two stars marked instead of one. The two would be so close together that no distinct space between them could be perceived by unaided vision. It is due to the magnifying power of the telescope, enlarging such small apparent distances, that the motion has been determined in so small a period as the 150 years during which accurate observations of the stars have been made.

PRIMITIVE METHODS OF DRILLING.

"A STUDY of the Primitive Methods of Drilling" is the title of a monograph by Mr. J. D. McGuire, in the recently-published Report of the United States National Museum (1894). The paper covers 125 pages of the Report, and is fully illustrated, in addition to which there are numerous references to books of travel among peoples living under the most primitive conditions. The author of the paper verified his opinions during the progress of the work by experiments in a laboratory fitted up for the purpose in the United States National Museum.

The paper discusses the various ways by which holes are bored in material, ranging from the softest to the hardest known, with such implements as were possessed by different peoples throughout the age of stone, and well through that of metal. The implements employed in performing the work were chiefly such as are on deposit in the Museum, the collections of which, especially from the North American tribes of Indians, are very rich. Yet the author has not hesitated, where circumstances warranted, to seek further afield for examples, notably in the concluding portion of the paper, where he describes a heretofore unrecognised drill, which frequently appears on the bases of royal seats among Egyptian antiquities. The act of cutting a hole through stone, or other substance, is shown to be a much simpler process than archæologists have heretofore supposed. The author has shown by specimens, and by quotations, that man, from the first time of which we have evidence of his existence, perforated with apparent ease material, such as shell or bone or ivory, and that to do this required nothing more than a stick or a stone with a little sand.

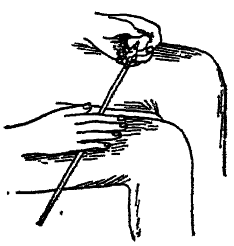

FIG. 1.—Horizontal drilling.

It is shown that early in the Lake period of Switzerland, a hollow cylinder of metal was often employed in boring stone axes, and the same conditions have existed from very early times in the history of the most ancient nations of which we have any records.

The seals of Mesopotamia, as well as the earliest intaglios, it is asserted, were bored with the drill and wheel from a period ante-dating the Christian era by thousands of years. The author shows that the American Indian, at the time of the discovery of the country, employed only the simple shaft-drill revolved between the extended palms of the hands, a method yet in use among the most primitive peoples in producing fire. The same implement, revolved horizontally upon the thigh, is illustrated in Fig. 1, by which means any of the simpler holes found in the earliest antiquities may be readily and quickly reproduced.

The "Bow Drill" (Fig. 2) is represented in the monograph as it has been employed by various races, ancient and modern, showing the manner of working it, and the differences in shape of the bow and shaft of the drill. The author calls attention to Fig. 3, which he says is the drill bow of ancient Egypt carried in sacred processions as an emblem of ceremony.

Fig. 4 is a drill of a complicated character used by certain California tribes, and appears to be an aboriginal American outgrowth of the "Pump Drill," which was imported into the country from Europe or Asia in modern times. The author illustrates what he designates as a "Top Drill" (Fig. 5), worked by means of a single strap and head-piece, which was developed in the course of his experiments. While in itself this drill is not claimed to be of any great value, it did lead to most interesting developments, the principle of which is, among other things, recognised in the Hindu statue of Samudra Mutu (the third incarnation of Vishnu). This again, in its turn, led to the recognition of the "Disc Drill" with double string, shown in Fig. 6, a most common glyph among early and late Egyptian antiquities known as the "S. S. M." or "Sam," which is by some authors thought to be "an altar typical of the Upper and Lower Nile joined under a single Pharaoh." Such a drill was set up in the Museum laboratory, and was found to work with perfect ease, and to be capable of producing any of the holes met with among the bored monumental stones of Egypt. The number of persons who, upon occasion, might be employed at the same time in working this drill, is unlimited; though probably not more than four would be required at any one time.

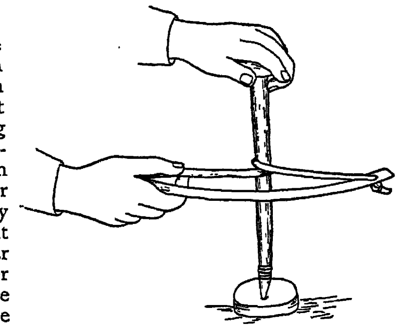

FIG. 2.—Single-handed Bow Drill in use.

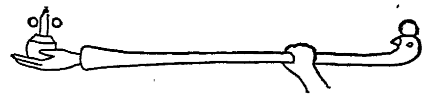

FIG. 3.—Ancient Egyptian Drill Bow.

The author not only tested the different stone points employed in boring stone and softer substances, but used the stone points themselves with sands of differing hardness upon different stones. Metal points to drills, as well as metal cylinders, were tested as to their cutting properties. Points of all kinds were experimented with, demonstrating that the sharp sand and wood points are capable of cutting a hole through any material, provided it was not harder than the sand. The paper shows the different characters of holes met with in objects of a prehistoric period, or by people in a low stage of mechanical development, and describes how such holes were made.

In most instances the exact number of revolutions per minute of each separate drill was recorded, and the character of cutting material was noted; the results were in every instance uniform. The velocity of revolution and hardness of the sand determined with mathematical accuracy the time required to drill a hole through any given material.

The striæ noticed upon the cores left in some holes bored in stone in Egypt had led distinguished Egyptologists to believe that the Egyptians possessed the diamond drill, with diamonds not only set in the lower edge of the cylinder, but on the outer and inner sides as well. Mr. McGuire's experiments have demonstrated that with such a drill as represented in Fig. 6, a hole of almost any diameter may be made through the hardest stone, and that the marks left on the interior of the drill-hole, or exterior of the core in the hole, is governed entirely by the hardness of the sand and size of its grains. The time requisite to perforate any material is shown to be but a fraction of what has been heretofore supposed necessary.

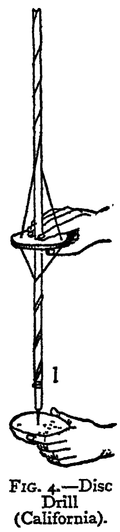

FIG. 4.—Disc Drill (California).

The paper proves the value of a study of the technology of archæology, and its necessity in any intelligent study of primitive implements. The manufacture of any product of ancient man

carries additional information to that which may be gathered merely from the shape of the article. Crushing stone, hammering or breaking it, by heat or cold, by pressure applied in any of the many known ways, each and every item of personal work has its value, and no one can say in advance to what its inspection may lead. We gather here, if the author be correct in his claims, data which no one could have anticipated in advance of experiments.

The long-stone drill points are found unsuited to boring substances which wood and dry sand will cut with ease. Soft wood is shown to be as unsuited as is hard wood for drill shafts. The hard stone point is found to cut steatite or wood quite

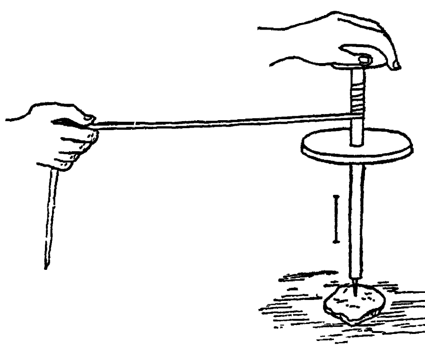

FIG 5.—Top Drill

readily, but is easily broken if it is attempted to bore hard stone with it. The study has been a careful one, has extended over a long period, and no known source of information has been intentionally neglected. Personal acquaintance with drills and their workings, as developed in the paper, is calculated to familiarise one with the Australian or American producing fire with the plain shaft-drill. It enables us to see in a new light Ulysses and his companions boring the eye from the Cyclops king. It gives a new interpretation to one of the incarnations of Vishnu. The remark of the latter, that their foes "should share their toil," suggests further, that instead of the "Nile gods" being

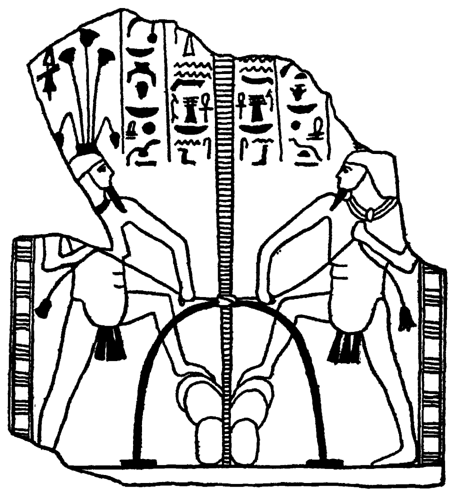

FIG. 6.—Disc Drill on Base of Statue of Amennembat.

shown in Fig. 6, we see the citizens of a subjugated territory performing ordinary menial labour. The so-called "gods" themselves are usually females, Negro or Asiatic, who hold the straps of the drill. It will be interesting to inquire whether under the late Nubian dynasty the Negro disappears from the work, and the Egyptian takes the subordinate place when the latter became subject to the Negro dynasty. The drill represented in the closing pages of the paper is capable of performing more and better work in boring stone than any other known hand-implement, either of ancient or modern date. This drill familiarises us somewhat with the high degree of skill possessed by the Egyptian workman of a remote antiquity. The author, in reproducing the Egyptian drill, has no doubts as to the identity of its shaft, its disc, the straps used to revolve it, or of the principle upon which it worked. He also believes that it was braced in some way. The bracing and method of tightening down the braces, invariably accompanying the drill, and even the possibility of the shafts having been tautened by strings or straps, are matters not satisfactorily interpreted. It will be a matter of interest to have more examples of this implement, which acquaints us with the man of Ancient Egypt in possession of a very complicated machine at a period in the life of the nation centuries prior to any date heretofore suggested. The scarcity of works and photographs on Egypt accessible to the author, prevents the hope that he may further interpret with available material the braces and means of tightening down this drill; but it is suggested that, in Europe and the East, there may be found sufficient data to answer this enigma.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Prof. W. J. Sollas, F.R.S., has been appointed a delegate to attend the International Geological Congress to be held at St. Petersburg in August or September next.

The following examiners for the Honour School of Natural Science have been appointed:—Physics: Mr. S. A. F. White. Chemistry: Mr. V. H. Veley, F.R.S. Physiology: Prof. F. Gotch, F.R.S. Morphology: Mr. G. C. Bourne, Mr. Adam Sedgwick, F.R.S. Botany: Mr. P. Groom, Mr. R. W. Phillips. Geology: Prof. W. J. Sollas, F.R.S., Dr. J. W. Gregory.

There are thirty-eight entries this year in Natural Science; eighteen of these are in physiology, twelve in chemistry, three in animal morphology and physics respectively, and two in geology.

The degree of Honorary M.A. has been conferred upon the Mayor of Oxford, Alderman Buckell, J.P. This is the first time that the University has conferred a degree on the Mayor of the city.

Miss Kingsley gave a public lecture at Manchester College on Friday last, on "The Connection of Fetish with West African Customary Law: a Study in Primitive Religion."

CAMBRIDGE.—The Rev. Prof. Wiltshire has presented to the Woodwardian Museum his valuable geological library, consisting of about 600 volumes and 900 pamphlets.

Prof. Macalister announces a course in Osteology, and Mr. J. E. Marr a course in Practical Geology, in the ensuing Long Vacation.

The Council of the Senate propose the re-establishment of the Professorship of Chinese, held by the late Sir Thomas F. Wade. It is understood that a distinguished Chinese scholar is willing to accept the office without stipend, and to undertake the charge of the magnificent collection of Chinese books given to the University by the late Professor. The collection is said to be unmatched in Europe, and probably in China.

The examination in Agricultural Science for the University's diploma will be held from July 5 to July 12.

The degree of LL.D. is to be conferred on Colonel Maharaj Dhiraj Sir Pratap Singh, K.C.S.I., as representing India, on June 17, when the Colonial Premiers are to receive honorary degrees.

A grant of 300*l.* from the Worts Fund has been made to Dr. A. C. Haddon, towards the expenses of an anthropological expedition to the Torres Straits. It is understood that Dr. Haddon will be accompanied by two or three other Cambridge men skilled in various branches of anthropological research, and by an expert in the Melanesian languages.

A grant of 100*l.* has also been made to Mr. H. H. W. Pearson for botanical research in Ceylon.

Dr. Humphry, Dr. Foxwell, Dr. Sidney Martin, and Dr. Mitchell Bruce have been appointed Examiners in Medicine; Dr. Phillips and Dr. Cullingworth, Examiners in Midwifery; and Mr. Pitts, Mr. Bennett, Mr. Watson-Cheyne, and Mr. Golding-Bird, Examiners in Surgery for the ensuing year.

THE London Technical Education Board has appointed Dr. J. O. W. Barratt to the scholarship in sanitary science. Dr. Barratt will commence his research work under the pathological superintendent at Claybury Asylum during the present summer.

THERE can be no doubt that some of the polytechnic institutions in London are moving towards a higher educational status than they occupied a few years ago. The courses of study are systematised, and they are supervised by teachers who have had laboratory experience; hence they educate the mind as well as train the hand. An announcement that, in the next session (1897-98) Principal Tomlinson, F.R.S., of the South-west London Polytechnic, will establish a class for training in research, affords an instance of the higher tendency of polytechnic instruction. This research training will form part of the curriculum of the second year day electrical engineering students of the institute, but will be open to a limited number of other students provided they can show a fair knowledge of the elementary principles of physics and mathematics. The method of conducting any research will be as follows:—The Principal will first select some subject for investigation suitable for electrical engineering students. He will then fully explain to the class the various reasons which have induced him to make the selection, and will give a brief history of what has been previously done round and about the subject, and full reference thereto. He will also propound a mode or modes of attacking the research, and invite criticisms from the class. When the best mode of attack has been decided on, the class will be expected not only to take part in the experiments, but to help in preparing the required apparatus. Should the results obtained be of sufficient importance, they will be offered in the form of a paper to such societies as the Royal Society, the Physical Society, or the Institution of Electrical Engineers. From time to time during the investigations the Principal will give demonstrations or lectures on those particular branches of magnetism and electricity which bear directly on the investigation, and will illustrate them by the results obtained. The subject selected for the first research is "the effect of repeated heating on the magnetic permeability and electrical conductivity of iron and steel."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 13.—"On the Passage of Heat between Metal Surfaces and Liquids in contact with them." By T. E. Stanton, M.Sc. Received April 7.

An experimental investigation was undertaken to determine the rate of transmission of heat from the walls of a heated metal pipe to colder water flowing through it. By means of the apparatus constructed for this purpose the velocity, initial and final temperatures, and pressure of the water, also the surface temperature of the pipe, could be observed; and by varying the initial temperature and velocity of the water, the effect of varying ranges of temperature and velocity of water could be experimentally studied.

The results of the experiments showed that the heat transmitted from any small surface of the pipe

(1) was independent of the pressure of the water;
(2) was proportional to the range of temperature between the surface and the flowing water;
(3) was *approximately* proportional to the velocity of the water;
(4) was proportional to a function of the viscosity of the water; or, putting

H = heat transmitted, S = surface of pipe,
V = velocity of water, T_0 = surface temperature of pipe,
t = temperature of water,

that $$\frac{dH}{dS} = k.(T_0 - t)V^m(1 + aT_0)(1 + \beta t)$$
where $m = \cdot 85$ $a = \cdot 004$ $\beta = \cdot 01$.

It is also shown that these results are in accordance with Prof. Osborne Reynolds' theory of the convection of heat from a hot surface to water flowing over it, this theory being that the motion of heat in the pipe follows the same law as the motion of momentum, as far as convection and conduction are concerned; so that, from Prof. Reynolds' equation for the fall of pressure in a pipe, the value of the slope of temperature may be expressed, the constants in which may be determined by experiment.

In this theoretical expression for the slope of temperature it is seen that the effect of the velocity of the water is very small, which is the most remarkable fact brought out by the experimental research.

"On the Magnetisation Limit of Iron." By Henry Wilde, F.R.S. Received April 3.

In a former paper read before the Society, "On the Influence of Temperature on the Magnetisation of Iron," the author described a new method of determining the magnetisation limit of magnetic substancцs, by which, with a single pole of an electro-magnet, a more exalted degree of magnetisation was indicated, as measured by the force of traction, than had previously been attained (*Roy. Soc. Proc.*, 1891, vol. l.). The magnetisation limit of iron, as deduced from his experiments, was 381 pounds per square inch of section, and it appeared to him at the time that the extreme limit was well within 400 pounds per square inch. The author has recently had occasion to repeat these experiments with other specimens of iron of different lengths, and has increased the magnetisation limit to 422 pounds per square inch, or 29·67 kilos. per square centimetre. He describes an experiment showing that the single-pole method of determining the magnetisation limit of magnetic substances compares favourably with the double-pole method, and that no higher degree of tractive force is to be expected from the latter than has been obtained from the former method.

Linnean Society, May 6.—Dr. A. Günther, F.R.S., President, in the chair.—Prof. Ludwig Radlkofer, of Munich, was elected a Foreign Member.—Prof. Stewart, F.R.S., exhibited and made remarks on some anatomical preparations showing the different modes of attachment of the *Ligamentum nuchæ* in herbivorous and carnivorous mammals, as exemplified in the sheep and dog, and of the *Ligamenta subflava*. The analogous ligaments of birds were dealt with, and special attention was drawn to a preparation of the vertebral column of the python, showing *vertebra-costal fibro-cartilaginous plates* of which he could find no description and which he believed to be peculiar to the Ophidia.—The Secretary read the abstract of a paper by Messrs. W. and G. S. West, on Desmids from Singapore. These had been discovered in a small collection of Algæ forwarded by Mr. H. N. Ridley from Singapore, and, in addition to seven species previously known from Sumatra, contained several which were new, and now described and figured.—Prof. Newton, F.R.S., communicated a paper by Captain F. W. Hutton, Curator of the Canterbury Museum, Christchurch, N.Z., entitled "The Problem of Utility," in which the views of Dr. A. R. Wallace on "The Utility of Specific Characters" (*Journ. Linn. Soc. Zool.*, xxv. pp. 481-496) were criticised, chiefly as tested by the study of the fruit-pigeons (*Ptilopus*).—The Secretary gave an account of a paper by the Rev. R. Bogg Watson, on some new species of Mollusca from the Island of Madeira, prefacing his remarks with a brief *résumé* of the researches previously made in the same direction by Messrs. Lowe, Wollaston, and other conchologists.

Chemical Society, May 20.—Prof. Dewar, President, in the chair.—The following papers were read:—The theory of osmotic pressure and the hypothesis of electrolytic dissociation, by H. Crompton. It is shown that van 't Hoff's view—that the osmotic pressure of a dissolved substance in dilute solution is equal to the pressure which the substance would exercise in the same volume if gaseous—holds when the dissolved substance and the solvent form normal or monomolecular liquids, and may hold when both liquids are associated, but does not hold when one only of the two liquids is associated. When either solvent or dissolved substance is associated, van 't Hoff's formula for the molecular reduction of the freezing point requires modification; on working with the modified formula, it is found that the results obtained accord with the view that electrolytes are monomolecular compounds dissolved in an associated solvent, namely water. The hypothesis of electrolytic dissociation is thus unnecessary for explaining cases of this kind, and is further inconsistent with what is known of the molecular character of liquids. The cube of the association factor of a liquid is approximately proportional to its specific inductive capacity.—Molecular rotations of optically active salts, by H. Crompton. The fact that optically active salts of strong acids have the same equivalent rotations in dilute solution is generally quoted in support of the dissociation hypothesis; the author shows, however, that similar regularities are observed in the case of other salts which are certainly not electrolytically dissociated, so that it would seem that monomolecular salts containing a common optically active radicle have the same equivalent rotation.—Heats of neutralisation of acids and bases in dilute aqueous solution, by H. Crompton. The author explains the constancy

of the heat of neutralisation of an acid by a base with the aid of the views developed in the preceding papers, and thus again shows that the electrolytic dissociation hypothesis is unnecessary. —A comparative crystallographical study of the normal selenates of potassium, rubidium and cæsium, by A. E. Tutton. The author is enabled, from the results of a very complete crystallographic examination of the selenates of potassium, rubidium and cæsium, to extend his previous conclusions deduced from a study of the sulphates and double sulphates of these three alkali metals; he shows that the characters of the crystals of isomorphous series are functions of the atomic weight of the interchangeable elements, belonging to the same family group, which give rise to the series.—The platinum-silver alloys; their solubility in nitric acid, by J. Spiller. The usual statement that, on dissolving platinum-silver alloys in nitric acid, from 5 to 9 per cent. of platinum dissolves with the silver, seems erroneous; the author only succeeded in causing about 1 per cent. of platinum to accompany the silver into solution. —Dalton's law in solutions. The molecular depression of mixtures of non-electrolytes, by M. Wilderman.—The action of bromdiphenylmethane on ethyl sodacetoacetate, by G. G. Henderson and M. A. Parker.

EDINBURGH.

Royal Society, May 17.—Sir Arthur Mitchell, K.C.B., in the chair.—An obituary notice of the late Dr. E. Sang was read by J. Bruce Peebles, Esq., in which he emphasised the desirability of the purchase by Government, or some learned Society, of Dr. Sang's invaluable logarithmic tables.—Dschâbir Ben Hayyán, and the chemical writings ascribed to him. Part ii., by Prof. John Ferguson.—A communication was read by Percy H. Grimshaw, on some type specimens of Lepidoptera and Coleoptera in the Edinburgh Museum of Science and Art. The paper dealt with 52 species of butterflies and 19 of beetles, the type specimens of which had been discovered by the author in a collection purchased by Edinburgh University from M. Dufresne, of Paris, in 1819, and afterwards transferred to the museum. The most important results embodied in the paper are as follows. One of the beetles has been found to be the type of a new genus, the specimen in question being probably unique; it has been found necessary to re-name one species of butterfly and one beetle; errors have been corrected in synonymy, &c., in the case of 19 species; and 8 species hitherto wrongly placed have been referred to their proper genera. The type specimens, together with coloured drawings, by Mr. Grimshaw, of the more important, were exhibited at the meeting. The same author read a short account of a melanic specimen of *Hestina nama*, Doubleday, which had been found in a small collection of butterflies purchased by the museum in 1890. The specimen described is very close, indeed to the aberration named by Oberthür *melanina* ("Études d'Entomologie," xx. 1896, p. 30, tab. 10, No. 177), but differs in several particulars, being generally of a darker tint, the inner series of white markings on the fore wing, and the ferruginous border of the hind wing being absent. The specimen and a coloured drawing of the same were exhibited.

PARIS.

Academy of Sciences, May 31.—M. A. Chatin in the chair.—New studies concerning the history of the lunar surface, by MM. Lœwy and Puiseux.—On the disaggregation of comets. Effect of Jupiter upon short-period comets, by M. O. Callandreau. Regarding a comet as consisting of a swarm of particles of spherical form, the density either being constant or varying only with the distance from the centre of the swarm, an expression is theoretically deduced giving the relations which should exist between the distance from the sun, the velocity, the ratio of the product of the masses of the sun and comet to the attraction constant, and the limiting radius of the orbit of an external particle. Under certain conditions the combined effect upon the disaggregation of the comet of the sun and Jupiter, near aphelion, may exceed that of the sun near perihelion.—Gradual flow of liquids in channels of large section. Fundamental equations, by M. J. Boussinesq.—On the liquefaction of fluorine, by MM. H. Moissan and J. Dewar (see p. 126).—On the function of humic materials in the fertility of soils, by M. Armand Gautier.—Physiological researches on the *sphincter ani* muscle, peculiarity shown by its reflex innervation and contraction, by MM. S. Arloing and Edouard Chantre.—M. Bouquet de la Grye announced to the Academy the loss it had sustained by the death of M. Léopold Manen, Correspondant for the Section of Geography and Navigation.—Report on the precautions necessary in the installation of electric conductors in the neighbourhood of powder magazines. The Committee report that no distinction can be drawn between telephone or telegraph wires and electric light mains. A distance of 10 metres would appear to be sufficient to avoid all risk with underground wires. The same distance is necessary in the case of water and gas pipes, as under certain conditions of leakage from neighbouring conductors they may become dangerous. For overhead lines a much greater distance is advisable, at least 20 metres.—Action of zinc and other metals upon the photographic plate, by M. R. Colson.—On partial differential equations of the second order the two systems of characteristics of which are confused, by M. E. von Weber.—On systems of complex numbers, by M. E. Cartan.—On the convergence of uniform substitutions, by M. E. M. Lémeray.—On the small periodic movements of systems, by M. P. Painlevé.—On the efficiency of gears, by M. L. Lecornu.—On a means of recognising a good cryoscopic method, by M. Ponsot.—On the purification of cerium, by MM. Wyrouboff and A. Verneuil. The oxides arising from the ignition of the oxalates are dissolved in nitric acid, and ammonium nitrate added in certain proportions to the warm solution. The whole of the cerium existing as Ce_3O_4 is precipitated as a basic nitrate which contains neither didymium, lanthanum, nor yttrium earths.—Remarks by M. Moissan on the preceding paper. By fractionally dissolving impure cerium carbide in dilute acids, the solution obtained furnished on simple calcination a perfectly white oxide of cerium. — On the alloys of the silver-copper group, by M. F. Osmond.—The phosphorescence of strontium sulphide, by M. José Rodriguez Mourels.—Contribution to the study of the preparation of ordinary ether, by M. L. Prunier. The presence of sulphur dioxide among the usual products of the crude ether distillate, is accounted for by the formation of ethyl isethionate, $CH_2.OH.CH_2.SO_2.OC_2H_5$, which splits up at 140° into SO_2 and alcohol.—On some combinations of phenylhydrazine with metallic chlorides, by MM. J. Ville and J. Moitessier.—Apparatus for the commercial analysis of gases, by M. Léo Vignon. The apparatus is of the Orsatt type; but calculations are given, taking into account the effects of the dead space, so considerable in this class of instrument.—On the products of decomposition of calcium carbide, and on its employment as a phylloxericide, by M. E. Chuard. After the acetylene has been produced by the action of water, ammonia continues to be slowly given off. By preparing a carbide rich in phosphide, a phosphocarbide is produced possessing exceptionally powerful insecticidal properties.—New order of Insectivora of the middle Miocene at Grive-Saint-Alban (Isère), by M. Claude Gaillard.—A self-recording balance, by M. G. Weiss. Designed more especially for physiological purposes. —Remarks on the preceding paper, by M. Bouchard.—On the umbilical vesicule of the Cheiroptera, by M. Mathias Duval.—Medical statistics of the army of occupation at Cochin China, by M. Bonnafy.—On cases of radiographic erythema of the hands, by MM. Paul Richer and Albert Londe.—On the application of photography to the registration of effluvia given off by living beings in both normal and pathological states, by MM. Luys and David.—On aurora borealis, by M. E. M. Pozzi.—On a general equation of fluids, by M. G. Perry.

NEW SOUTH WALES.

Linnean Society, March 31.—The President, Mr. Henry Deane, in the chair.—The President delivered the annual address. The special subject of the address was an expansion of matters treated of in that of the previous year, namely, a consideration of the relations of the fauna and flora of Australia to those of other parts of the Southern Hemisphere. The affinities of the floras of the Cape of Good Hope and of West Australia; of South-eastern Australia and New Zealand, and of South America; and the discovery of fossil marsupials of an Australoid type in La Plata and Patagonia were passed in review; and the important bearing of evidence of this kind on the question of former possible land-connections between these countries where now deep seas are believed to exist, was discussed. Other cognate subjects touched upon were the moot subject of the permanence of ocean basins and continental areas; the present state of knowledge of the rigidity of the earth; and the causes of extreme changes of climate in past geological ages. The address concluded with some references to the earliest known dicotyledonous plants in

Australia and Europe.—Prof. J. T. Wilson was elected President for the current year.

Monthly Meeting.—Prof. Wilson, President, in the chair.—Descriptions of new Australian Lepidoptera, with notes on synonymy, by Oswald B. Lower. Twenty-six species referable to the sections Bombycina, Geometrina, Noctuina, Pyralidina and Tineina, were described as new.—Studies in Australian entomology, No. 8. Descriptions of two new Tiger-beetles, by T. G. Sloane. A new species of *Megacephala* from West Australia and of *Tetracha* from Barrow Creek, Northern Territory of South Australia, were described.—Notes on Australian fungi, by D. McAlpine. Ten species were added to the cryptogamic flora of New South Wales, of which six were described as new, and four were recorded for the first time, one of them in association with a new host.

DIARY OF SOCIETIES.

THURSDAY, JUNE 10.

MATHEMATICAL SOCIETY, at 8.—Models of the Regular Convex and Star Solids: W. W. Taylor.—The Calculus of Equivalent Statements (Sixth Paper): H. MacColl.—On the Primitive Substitution Groups of Degree Fifteen: Dr. G. A. Miller.—A Generalised Form of the Binomial Theorem: Rev. F. H. Jackson.

FRIDAY, JUNE 11.

ROYAL INSTITUTION, at 9.—Diamonds: W. Crookes, F.R.S.

ROYAL ASTRONOMICAL SOCIETY, at 8.—Theory of the Motion of the Moon; Note on the Mean Motions of the Lunar Perigee and Node: Prof. E. W. Brown.—Elements of Comet Perrine (*f*) 1896 November 2: C. J. Merfield.—Nebula ℍ I. 43 Virginis: Prof. K. D. Naegamvala.—The Shower of Leonids in 1897: W. F. Denning.—Results of Double Star Measures with the 8-inch Equatorial at Windsor, New South Wales, in 1896: John Tebbutt.—*Probable* Papers: Notes on the Reduction of Stellar Photographs: A. A. Rambaut.—Photographic Observation of Comet *b*, 1896: A. A. Rambaut.

PHYSICAL SOCIETY, at 5.—The Effect of Sea-water on Induction Telegraphy: C. S. Whitehead.—A New Definition of Focal Length, and an Instrument for its Determination: Thomas H. Blakesley.—On the Decomposition of Silver Salts under Pressure: Dr. J. E. Myers and Dr. F. Braun.—On a New Way of determining Hysteresis in Straight Strips: Dr. Fleming, F.R.S.

MALACOLOGICAL SOCIETY, at 8.

SATURDAY, JUNE 12.

ROYAL BOTANIC SOCIETY, at 4.

LONDON GEOLOGICAL FIELD CLASS.—Excursion—Coulsdon to Merstham. Lower Chalk. Leave Cannon Street, 2.17; arrive Coulsdon, 2.59.

MONDAY, JUNE 14.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—Note on a Possible Danger from Fire involved in the Transport of Barium Peroxide in Wooden Barrels: Dr. A. Dupré, F.R.S.—The Valuation of Commercial Nitrate of Soda: Dr. Pauli.—Recent Improvements in Smokeless Compounds and in Processes of Manufacture: Hudson Maxim.—Comparative Experiments on the Estimation of Phosphoric Acid: Alexander Cameron.—The Strength of Commercial Formaldehyde Solutions: W. A. Davis.

TUESDAY, JUNE 15.

ZOOLOGICAL SOCIETY, at 8.30.—On the Mammals obtained by Mr. John Whitehead during his Recent Expedition to the Philippines. With Field-Notes by the Collector: Oldfield Thomas.—On the Presence of Ribs in *Polyodon* (*Spatularia*) *folium*: Prof. T. W. Bridge.—On the Spiders of the Family *Theraphosidæ* (*Mygalidæ*) from the Ethiopian Region, contained in the Collection of the British Museum: R. I. Pocock.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.

WEDNESDAY, JUNE 16.

ROYAL METEOROLOGICAL SOCIETY (Burlington House), at 4.30.—The Non-Instrumental Meteorology of London, 1713–1896: R. C. Mossman.—Hailstorm in the South-West of London, April 27, 1897: Charles Harding.

ROYAL MICROSCOPICAL SOCIETY, at 7.30.—Exhibition of Palates of Molluscs from a Collection recently presented by Mr. C. Rousselet.

THURSDAY, JUNE 17.

ROYAL SOCIETY, at 4.30.

LINNEAN SOCIETY, at 8.—On the Distribution of *Primula elatior*, Jacq.: Miller Christy.—On the Acari collected by Mr. H. Fisher, Naturalist of the Jackson-Harmsworth Polar Expedition, at Cape Flora, Northbrook Island, Franz-Josef Archipelago, in 1896: A. D. Michael.—Further Observations on Stipules: Sir John Lubbock, Bart., F.R.S.—On Minor Tension Lines between Plant Formations: Prof. Conway Macmillan.

CHEMICAL SOCIETY, at 8.—Ballot for the Election of Fellows.—The Reduction of Perthiocyanic Acid: F. D. Chattaway and H. P. Stevens.—Molecular Refraction of Dissolved Salts and Acids, Part II.: Dr. J. H. Gladstone, F.R.S., and W. Hibbert.—On a Space Formula for Benzene: Prof. J. Norman Collie, F.R.S.—On the Production of some Nitro- and Amido-oxypicolines: Dr. A. Lapworth and Prof. J. Norman Collie, F.R.S.—The so-called Hydrates of Iso-propyl Alcohol; Dr. T. E. Thorpe, F.R.S.—The Carbohydrates of the Cereal Straws: C. F. Cross, E. J. Bevan, and C. Smith.—Further Experiments on the Absorption of Moisture by Deliquescent Substances: H. Wilson Hake.

MINERALOGICAL SOCIETY, at 8.—On Blödite from the Punjáb: F. R. Mallet.—On Monazite and Xenolime in European Rocks: Orville A. Derby.—On the Identity of Sundtite and Webnerite: G. T. Prior and L. J. Spencer.

FRIDAY, JUNE 18.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Sub-Oceanic Changes: Prof. John Milne, F.R.S.

SATURDAY, JUNE 19.

GEOLOGISTS' ASSOCIATION—Excursion to Leighton Buzzard. Director: A. C. G. Cameron. Leave Euston, 9.10 a.m.; arrive Leighton, 10.47 a.m.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—The Naturalist in Australia: W. Saville-Kent (Chapman).—Scientific Romances: C. H. Hinton, second series (Sonnenschein).—Waste and Repair in Modern Life: Dr. Robson Roose (Murray).—W. and A. K. Johnston's Geological Map of the British Isles, revised edition (Johnston).—Mineralogical Geology. A Synopsis for the use of Students, to accompany ditto: A. Johnstone (Johnston).—Smithsonian Institution. Annual Report to July 1895 (Washington).—U.S. Department of Agriculture. Weather Bureau. Report of the Chief of the Weather Bureau, 1895–96 (Washington).

PAMPHLETS.—Adriades: P. Pasinii (Venitüs, Visentini).—The Monetary Situation in 1897: G. M. Boissevain (Macmillan).

SERIALS.—Strand Magazine, June (Newnes).—Middlesex Hospital Journal, No. 3 (London).—Journal of the Anthropological Institute, May (K. Paul).—Catalogus Mammalium, nova editio, Fasc. 2 (Berolini, Friedländer).—Bulletin de l'Académie Royale des Sciences, &c., de Belgique, 1897, No. 4 (Bruxelles).—Memoirs and Proceedings of the Manchester Literary and Philosophical Society, Vol. 41, Part 3 (Manchester).—Observatory, June (Taylor).—Himmel und Erde, May (Berlin, Paetel).—Atlantic Monthly, June (Gay).—Annals of the Astronomical Observatory of Harvard College, Vol. xxviii. Part 1 (Cambridge, Mass., Wilson).—Ditto, Vol. xxxvi. (Waterville, Me.).—Fortnightly Review, June (Chapman).

CONTENTS.

THURSDAY, JUNE 17, 1897.

PROFESSOR KLEIN AND TECHNICAL EDUCATION IN GERMANY.

A MOVEMENT regarding the higher technical education in Germany was started a few years ago by Prof. Klein, in conjunction with some of his colleagues (Nernst and others) at the University of Göttingen, which may become a most important factor in the development of technical education as well as of science. It has, however, from the very outset, met with violent opposition, both in University and in engineering circles.

An account of Prof. Klein's scheme, and of the discussion to which it has given rise, cannot fail to be of interest to all concerned with technical education.

The first publication of Klein's on this subject is contained in the lithographed memoir dated Easter 1895, and which has been published in the *Zeitschrift des Vereins Deutscher Ingenieure*, January 1896. In it is proposed the establishment of a physico-technical institute at the University of Göttingen.

The object of this institute he states to be to give opportunity to persons who already possess a certain amount of scientific or technical education to increase both their knowledge and their power of using it.

It is not intended for the education of large numbers, but rather to help the exceptional few who, in consequence of their talents or other favourable circumstances, can spend more time on their education.

Or, as it stands in the original—

"Das zu gründende Institut soll wissenschaftlich oder technich bereits bis zu einem gewissen Grade vorgebildeten Personen Gelegenheit zu weiterer Vertiefung ihres Wissens und Könnens auf physikalisch-technischem Gebiete liefern. Hierbei wird es sich nie um Massen ausbildung, sondern nur um die Förderung einiger Weniger handeln, denen Talent oder sonstige glüchliche Umstände ein Uebriges auf ihre Ausbildung zu wenden gestatten."

The projected institute should combine all the appliances of modern physics with those technically used, but so that the first are subservient to the latter.

In physics the study of nature is nearly always conducted with experiments carried out in the smallest dimensions, whilst the engineer works towards the mastery over nature on the largest scale. The institute should combine both *micro-* and *macro-physics*.

The following are given as the more important departments of the institute: "Precisions-Mechanik" (measuring instruments); theory of elasticity and strength of material; kinematics, including hydraulics and experimental ballistics; practical thermo-dynamics and practical electricity.

It is added that it will scarcely be possible to establish all these at once.

Lectures of a practical nature are to be added on all the subjects.

The importance of practice in drawing and construction is also dwelt upon. The chief thing, however, will be the work in the laboratory.

It is pointed out that this scheme will enable the engineer to take a University degree by a scientific thesis on some technical subject.

The qualifications of a director and an estimate of the necessary expenditure are next discussed. The latter is put down at about 15,000*l.* as the initial expense, and the annual cost as 750*l.*, exclusive of the director's salary.

Then follows a more minute discussion of the plan and its relation to the Reichsanstalt in Charlottenburg, its connection with the University, the advisability of such an institute from the engineer's point of view, the benefit it will be to the University, and the suitability of Göttingen for such an institute.

The first thing which will strike every one in reading this will be that there is nothing more proposed here than is, or might be, carried out in many of the higher technical schools, and that the whole has been devised at the University somewhat in ignorance of what the technical schools are doing. Nothing, therefore, seems more natural than that from these a unanimous voice against it should have been raised. Klein himself has fully acknowledged this defect in this first statement of his scheme.

To form a true idea both of his high aims and of their importance for technical education, it is necessary to enter into the criticism already mentioned, which the plan has received from engineers and engineering professors, and into a number of further publications by Klein on the subject, mostly addresses read at meetings of engineers and teachers.

A perusal of these papers brings out clearly the following points.

There has grown up in Germany a strong feeling of antagonism between the technical high schools ("Technische Hochschule" is the name now generally given in Germany to the colleges devoted to higher technical education) and the Universities. The new life infused into Germany since its unification, and the great impulse given thereby to German industries, has naturally had its influence on the technical high schools and on technical education in general; but the Universities have remained almost uninfluenced by it. They have remained stationary whilst the others have progressed, and the engineers have more than ever looked with sovereign contempt on these ancient and, to their minds, fossilised seats of learning.

But their progress has been hampered by the unsatisfactory preliminary preparation of the students on entering on their technical studies, and so the whole question of secondary education comes in, just as it does in England. To remedy this, and make the school teaching less classical, and to bring it into closer connection with the requirements of modern life, the technical high schools now claim that the teachers of mathematics and science should be educated by them, and not at the Universities. At the same time, they feel the need of attaching to themselves, or where they exist already to extend, just such laboratories as Klein described, and they maintain that these can only be useful to the development of industry if they are under their direction, and further, that any money given by the Government to the Universities would be taken from *them* and utterly wasted.

There has also been going on a gradual reformation in the programmes recommended to the students, and an endeavour to restrict the purely theoretical parts, and to dwell more on the increase of power in the students to

apply their knowledge instead of increasing the knowledge itself, and altogether to bring the teaching into closer connection with practical needs; to increase the *Können* as opposed to the *Wissen*.

It may be mentioned here that the engineering course in Germany extends over four years, and the students generally enter about the age of eighteen, having, as a rule, spent one year at works beforehand; so that they do not enter practical life till they have, on an average, reached an age of about twenty-three years or more, as one year of military service has to be taken into account. Even then those who want to enter into the service of the State are tied down by the necessity of passing a final examination at about the age of twenty-seven.

It is felt that this age is altogether too high, and to remedy this requires, in the opinion of the technical professors, that the students should be better prepared at school, so that the more elementary part of mathematics and physics can be left out of their course.

The most active of these technical professors is Prof. Riedler, at Charlottenburg, who is well known in this country as a successful practical engineer. His plans for reform have been published in the *Zeitschrift*, 1896, and from recent numbers of the same periodical it becomes apparent that his proposals have in the main been carried out at Charlottenburg. In reading through these, one thing is very striking: a great deal of what he writes on the aims of the highest technical education might have been written by Klein in favour of his plans; in fact, Riedler lays it down as a necessary duty of the technical high schools to care for the highest scientific education of a few engineers.

He says already in 1895 (*Zeitschrift*, August 10, 1895), after discussing the needs of the average students, "Die Hochschule muss jedoch mehr bieten, sie muss einer beschränkten Zahl wissenchaftlich Begabter die höchste Stufe Mathematischer Bildung zu erwerben; aber diese muss eine fruchtbare sein und kann erst dem Fachwissenschaftlichen studium nachfolgen

"Die Universität Leipzig hat angeblich diese höchst zeitgemässe Aufgabe erfasst, sie wäre aber für die Technische Hochschule näher liegend. Wo sollen die Universitäten ins gesamt auch nur eine Lehrkraft hernehmen, die den Ingenieuren das versprochene und Nothwendige bieten könnte?"

Riedler develops his ideas still further in 1896 in several articles (*Zeitschrift*, pp. 301, 337, 374), and also criticises Klein's scheme, of course as a strong opponent.

From these quotations it is clear that he feels the same need for the highest technical education as Klein; but we may well turn his question round and ask where will he find a professor who can teach the *highest* mathematics to technical students, and who is at the same time a practical engineer? Here Klein comes in; his plan will help to educate such men.

Riedler has in these papers a fling at higher mathematics as cultivated at the Universities, where "Abel and Riemann" count much, where one lives in regions in which θ-functions disappear, and in hypo- or meta-geometry, where "dimensions cease and manifoldnesses begin," and where the student learns "gymnastics in four dimensions."

It is easy from a "practical" point of view to make light of many parts of pure mathematics. Even Klein professes that he has often had doubts whether those theories in which the mathematician delights are really worth the trouble of increasing and developing, and in his opinion they would not be if they should never be of use in application to physical and engineering problems.

But, he adds, he has always come away from such contemplations with the conviction that his (and all mathematicians') optimistic views are justified by the belie that they will assist in due time in subjugating nature to science. In fact, the history of science is so full of examples that it is unnecessary to quote any.

If Riedler should succeed in getting the influence of all those speculations banished from the Hochschule, these will soon become as fossilised as the Universities, in his opinion, are at present.

But let us return to Klein's plans. His chief idea, as gathered from the various papers and from his own expressions during his recent visit to England, can be stated briefly enough.

He wants to bring together again theory and practice; he wishes the Universities to take their proper place in modern German life, which differs from that of former days by its enormous energy in industry and commerce. He acknowledges that much has been done outside the Universities, and for purely practical purposes, to develop science; that altogether new methods of investigation have been invented by engineers, and not only in physical investigation but even in mathematics.

He wishes to introduce these at the Universities to enable them to fulfil their duties properly, and he hopes by thus raising these institutions to enable them so to develop science that the results will be practically useful and repay the debt to engineers which science now owes them.

But he also hopes greatly to improve the education of mathematical and science teachers. There can be no doubt that the chief education of these must and will remain in the hands of the Universities—that they cannot be left to the technical schools. It is quite impossible to establish schools exclusively for future engineers, because it is impossible to settle at an early age what career a boy will select, and the majority of schools must be of a general character.

But what is highly desirable is that all teachers, not only the scientific ones, should be better prepared in science, and should gain a higher idea of the value of practical work, and that the old spirit according to which education can only be gained through the old languages, should be broken.

Not only the would-be engineers, but all boys must be made to feel this change, and therefore all teachers must be imbued with modern notions. To have some educated at the University and some at the technical schools would intensify the existing antagonism between science and classics. This ideal education of teachers can only be obtained at the Universities, and here only if these are themselves modernised. Klein's scheme tends to bring this about; it does not exclude the possibility of some teachers of science and mathematics being educated at high schools, nor that many of these should spend a part of their time in studying at a high school; it would be easy to devise a plan by which this could be accomplished.

Klein also hopes to help the engineer directly. The problems taken up by University men are at present without direct connection with practical needs, simply because the latter are unknown at the Universities. Klein wants to make these needs known to the University teachers in order to make it possible to direct their energies in the channels useful to engineers. Again, by having at hand a technical laboratory, and having connected with this all the intellectual resources of the University, it will be possible to bring to bear on technical problems such scientific power as is not likely to be found elsewhere.

To the same end he wishes to make important English scientific papers on technical subjects accessible to German physicists and engineers through translations, and a beginning will be made with Prof. Osborne Reynolds' paper on "Friction of Lubricated Bearings." Dr. Routh's "Rigid Dynamics" will also be translated.

It will be seen from this that Klein's scheme does not affect the ordinary education of engineering students, but that he takes a far higher flight which will not affect the routine at the high schools. Indirectly it cannot fail to raise the whole profession, the whole education of Germany; and if it is carried out in the spirit in which it is conceived, and is ably supported by his colleagues, it will have far-reaching consequences.

That the original memorandum did not reveal the full meaning of Klein's scheme can be explained by supposing that he had himself suffered from the want of direct contact with the engineering profession, and, besides, by his taking it for granted that every one would understand that he was speaking only of the *highest* part of the education of engineers, and that he did not dream of establishing a new engineering school to compete with the old ones.

As soon as he became aware of the opposition raised, he tried by personal intercourse to put himself right, and to destroy the false impression originally created. He went to meetings of the Engineer's Verein at Aachen and Hanover, in 1895, and expounded his plans, with the result of converting many to his views. When he found that the high schools were preparing schemes for laboratories of their own, he at once gave up all idea of asking the Government for money, considering that here the high schools had the first claim, and set about to make private means available in English and American fashion. He succeeded in interesting influential and wealthy manufacturers in his cause, who formed a committee which has promised and guaranteed him a sum sufficient to start one laboratory. For this purpose the thermodynamic laboratory has been selected, and is now in course of erection. As to the choice of a director, he has asked Prof. Linde's advice, who has recommended a pupil of his own; and all will agree that Linde's name is sufficient guarantee that the new director has been educated in a truly practical spirit.

Prof. Klein's plan does not in the least collide with the legitimate aims of the technical high schools; such collision only takes place with regard to the education of teachers, and here the claims of Riedler and others seem to us to be altogether unreasonable.

Klein is altogether the right man to carry out the plan successfully. His singleness of mind is conspicuous to every one who has come, however slightly, in contact with him. As a mathematician he is known and honoured all the world over. He possesses a strong faculty for geometrical conceptions, and likes, with wonderful success, to clothe every mathematical investigation in a geometric garb, or to illustrate it geometrically. His book on the *Ikosaeder* is a brilliant example of this. He, more than any other, has tried to remain in contact with the school teachers of mathematics, and has often put the results of profound mathematical speculations in such a form that they become available for school teaching.

To make the teaching of geometry more real he started, when Professor at the Munich Technical High School, the modelling of surfaces by the students; and the whole large collection of models on sale by Brill in Darmstadt may be said to have grown out of this. For the same reason, he has introduced at the University a course of geometrical drawing. He dwells not less on the necessity of developing facility in performing arithmetical calculations.

All engineering teachers in England will wish that English schoolmasters had been drilled in these two directions.

By descent, and from the environments in which he grew up, he has, from his youth, been familiarised with industry and manufacture.

The traditions of Göttingen, too, are greatly in his favour, and have helped to ripen his plans. Here Gauss worked for years at all possible problems ranging from pure abstract theory of numbers to the invention of an electric telegraph, and of a method of signalling by the sun's rays, now so extensively used in the English army. He enriched science as well as engineering with many important gifts; the theory of least squares, the absolute measure of force, the theory of magnetism, and all his work in connection with Weber.

What Gauss did alone, that Klein wishes to continue in combination with others; he justly observes, also, that a small town is more suited for his experiment than a large town with all its distractions.

We can only wish him success in his bold undertaking, and feel sure that, even if German engineers should carry their antagonism so far as to try to starve his undertaking by preventing young men from making use of the opportunity he offers them, which is most improbable, there will come to him, as heretofore, many eager students from England and America. O. HENRICI.

A WELL-KNOWN TEXT-BOOK OF CHEMISTRY.

A Manual of Chemistry, Theoretical and Practical (based on Watts' edition of Fownes' Manual). By William A. Tilden, D.Sc., F.R.S. Pp. xvi + 599. (London: J. and A. Churchill, 1897.)

THE preface to the original edition of Fownes' *Manual* is dated October 5, 1847. The merits of that book, published about half a century ago, were known to all. But, inasmuch as Prof. Tilden says in his preface to the present work "the last traces of Fownes have disappeared in the process" of re-writing, it is a manual of chemistry by Dr. Tilden, and not Fownes' book, that is to be reviewed here.

The task undertaken by the reviewer is a difficult one. I have tried to discover the principles on which the book is constructed, and to follow the method whereby these principles are applied. I trust, and I expect, that the criticisms I make will not be regarded by the author as the flippancies of an irresponsible reviewer, but that he will believe I am serious and as anxious as he is, up to my lights, to promote the study of chemistry.

What is the subject-matter of chemistry? If I am justified in taking this book as (among other things) Dr. Tilden's answer to that question, then, in my opinion, the answer is wrong.

The opening sentence of the *Introduction* reads well.

"The science of chemistry has for its object the study of the composition of the materials out of which are formed the earth, the sea, the air, and the organised and living beings which inhabit them. Chemistry also seeks to explain the composition of bodies and their properties."

If this is taken with the statement on page 12,

"it is no longer sufficient to determine composition. The aim of the chemist is to ascertain the relation of composition to the physical properties of a body,"

we have a description of the subject-matter of chemistry which seems to me fairly adequate. Would it not have been better to have omitted the word *physical* in the last sentence of the words quoted?

But the book does not fulfil the promise of the *Introduction.* The study of the compositions of bodies; the study of the properties, especially the reactions, of bodies; and the study of the connections between the compositions and the properties of bodies; that, surely, is the business of chemistry. And the one method by which this business can be conducted successfully is the comparative method. If a student is to acquire a genuine knowledge of that branch of natural science called chemistry, it seems to me he must be led constantly to compare and contrast facts in order that he may be prepared to receive, and comprehend, the generalisations of the science. The foundation cannot be laid firmly unless the builder is thinking of the structure he means to raise upon it. To vary the illustration: if the student of chemistry has shot over him loads of sterilised facts he soon is smothered; and if attempts are made to restore him by drawing him out now and then and submitting him to a cold douche of theory, the spark of life that was left in him is likely to be washed away.

After carefully reading much of this book, I am driven to the conclusion that it fails to connect the facts it records with one another, and with the generalisations which rest on the facts, marshal these facts into order, and suggest other facts. Moreover it seems to me that the generalisations of the science are not stated with sufficient fulness, lucidity, and suggestiveness; that the hypotheses of chemistry are not enunciated in such a way as makes it possible for the student to hold them firmly in his mental grasp, and at the same time to be ready to let them go when they have served their purpose of aiding clear thinking; and that the theories of chemical science are not brought into just proportion with the facts and the hypotheses which they ought to bind together and to vitalise.

I admit the enormous difficulty of dealing accurately, lucidly, and suggestively with the vast quantity of facts that has been accumulated by the labours of generations of chemists. I admit the insuperable difficulty of fitting all the many hypotheses of chemistry into their proper places. I do not deny the impossibility of treating the theories of the science, especially in an elementary book, so as to command the assent of so fractious a fraternity as the chemists. Still I think that a serious and painstaking effort should be made by every writer of a manual of chemistry to compare and contrast facts with facts, and to show that the hypotheses and the theories of the science rest on, while they pass beyond, and illuminate, the facts of the science.

It would be manifestly unfair, even in a review to which the writer's name is attached, to find such fault with a book as I have found with Dr. Tilden's *Manual*, without going into some details to justify the fault-finding.

On pp. 16 to 20 a brief account is given of chemical nomenclature and notation. The facts regarding the compositions of compounds which are conveyed by chemical formulæ are expressed in these pages in the language of the theory of atoms. But that theory has not been explained to the student; it has been sketched in the merest outline only. Indeed the theory could not be explained at this early stage of the student's progress. This method seems to me to be entirely wrong; I am certain it cannot conduce to correct thinking.

The *Introduction* is followed by chapters wherein are recounted, and illustrated, the preparations, and some of the properties, of the non-metallic elements and their more important compounds. These chapters also contain lucidly written accounts of those general properties of gases which are of importance to the chemist; of the structure of flame; of some of the phenomena of solution; and of other important matters. Then follow chapters on the laws of combination, the atomic and molecular theory, classification, crystallisation, allotropy and isomerism, heat and chemical affinity, and electrolysis. These are succeeded by accounts of the preparations and properties of the metals and the compounds of the metals.

It is not with the chapters or paragraphs which convey information about the elements and their compounds that I find fault. Much, I think one may say most, of what is contained in these chapters is written clearly and accurately; a selection is made—I think on the whole a good selection—from the enormous number of those facts which are the building stones of the edifice of chemistry. What I complain of is that these building stones are not employed to construct a building; they are arranged in heaps, and each heap is duly labelled;—but, that is all. If chemistry is a collection of bundles of information loosely held together by a few strings of generalisation, then the method of this book is excellent. The separate pieces of information are conveyed in clear and accurate terms. But, in my opinion, the binding strings are very fragile and they do not prevent the contents of the bundles from being scattered.

Many of the chapters which deal with the principles of the science are unsatisfactory. The *laws relating to combining proportions* are enunciated on pp. 236 to 238 These laws are not stated in sharp and decisive terms For instance

"The *law of definite proportions* affirms that when two substances unite together to form a given compound they can unite only in a fixed proportion; . . ."

Why "*two substances*"? What exactly is "*in a fixed proportion*"? Why "they *can* unite"? Would not a student find much difficulty in understanding the conclusion that is drawn from the law of reciprocal proportions? This conclusion is

"For each element, therefore, there is a fixed proportion in which it enters into any state of chemical union."

The laws of chemical combination cannot be understood without the help of examples worked out fully from the basis of analytical and synthetical data. I cannot find in these pages any statement of the nature of the evidence whereon these fundamental laws rest; nor can I discover any suggestion of the vast importance of these generalised statements of facts—the laws of chemical combination—which we have every reason to regard as true natural laws.

On p. 238 sixteen lines are devoted to *the atomic theory of Dalton*. I am certain that no student could obtain, from the author's statement of this theory, a clear mental image of the Daltonian conception of the atom. On this page occurs the statement

"a group of atoms united together chemically is called a molecule."

And on p. 240, after the enunciation of the law of Avogadro, we read

"by a molecule is here understood a small portion of the substance of the gas made up of atoms which do not separate from one another during the movements of the molecule."

This is altogether insufficient. Reference is made, it is true, to "Kinetic Theory, p. 239"; but no clear and sufficiently detailed statement of what is to be understood by the word *molecule* is to be found in the paragraphs devoted to that theory.

As regards the methods employed for determining the relative weights of molecules and the relative weights of atoms, I do not think that a student of fair intelligence and perseverance will be able to realise these methods as definitely as they ought to be realised, even by a very careful consideration of the paragraphs devoted to these subjects on pp. 241 to 251. About 10 pp., 254 to 264, are concerned with the very difficult subject of *valency* or *atomic value* and the application thereof to constitutional formulæ.

". . . an atom of certain elements can replace or be substituted for only one atom of hydrogen, whereas the atoms of other elements can replace 2, 3, 4, &c., atoms of hydrogen."

Then follow reactions meant to illustrate this statement. And then we read

"This difference of combining or saturating power, originally called *atomicity*, now more appropriately called *valency*, is sometimes denoted by placing dashes . . ."

This is, in my opinion, slipshod and hazy writing, and it cannot but induce to slipshod and hazy thinking.

There is an extraordinary statement on pp. 255, 256 about *the law of even numbers*. This "law," we are told, is that

". . . in all such compounds [saturated or normal compounds] the sum of the perissad elements (that is, elements whose atoms are of uneven valency) is always an even number."

Take the case of the gaseous molecule NO. *The sum of the perissad elements*, to use the author's loose phrase, in this compound is not an even number. Perhaps this compound is not a "saturated or normal compound"? Well, define what you mean by "saturated or normal," and then show that *the law of even numbers* is of any value as an aid to accurate research and accurate thinking. The existence of the three gaseous molecules $InCl$, $InCl_2$, $InCl_3$ disposes of the law of even numbers, if the *law* is anything more than a mere playing with numbers.

I have tried to get some clear notions about *heat and chemical affinity* from the pages which deal with that subject; but I have failed. These pages give one a little information about some portions of thermal chemistry; but the subject of chemical affinity is not really touched on at all.

On p. 287 there is a guarded, but still misleading, statement which comes perilously near an enunciation of Berthelot's *law of maximum work*, which "law" is both false in fact and untrue in principle.

To sum up the complaints I make against this book. There is a want of proportion. There is a failure to appreciate the relative importance of the various parts of the science. There is a failure to describe facts of observation as such, and then to show how hypotheses arise and react on these facts, until a general theory is attained, which illuminates the foundations whereon it rests, and suggests the lines on which search must be made for more facts.

I admit the vast difficulty of writing an elementary manual of chemistry. The past is strewn with failures, to which I have myself contributed. I am exceedingly sorry to say that, in my opinion, this book is not a success.

M. M. PATTISON MUIR.

PHILOSOPHY AND PHILOSOPHERS.

History of Philosophy. By Prof. A. Weber. Translated by Dr. F. Thilly. Pp. xi + 630. (London: Longmans and Co., 1896.)

System der Philosophie. Von W. Wundt. Zweite umgearbeitete Auflage. Pp. xviii + 689. (Leipzig: Engelmann, 1897.)

FOR Prof. Weber the chief interest of his subject obviously lies in the post-Kantian schools, and his own solution of the problem of philosophy, as shaped by the influence of the conceptions and methods of the natural sciences on the one hand, and by the exigencies of ideal and optimist ethics on the other, is in the direction of a "concrete spiritualism." The key-word of this he finds in will or force rather than reason, but a *Wille zum Guten* in place of Schopenhauer's will to live. It is in virtue of his firm hold upon modern problems that his review of the way in which they have been historically evolved is so far successful that some, at least, of the dry bones of the History of Philosophy are made to live. Those writers whose antagonism to a dualist metaphysic makes them forerunners of the post-Kantian development—Bruno for example, and

more especially Spinoza and Leibniz—are exceptionally well treated, and of the teachers who drew their inspiration from Kant, Fichte and Herbart, and particularly Schelling and Schopenhauer, are handled sympathetically and with discrimination.

Prof. Weber's book has the defects of its qualities. The amount of space allotted to some of the greater philosophers, such as Plato and Aristotle, is restricted, and they are dealt with rather as exponents of phases in development than as thinkers whose positive solutions of the problem are of enduring interest. Thus the *Phædrus* is summed up as "opposing the selfish rhetoric of the sophists with the true eloquence of the philosopher, whose chief object is the knowledge of the invisible world." There is a technical mistake in saying that Aristotle's "first philosophy" has for its object "the queen of the categories—substance." The biological point of view, which is so pronounced in Aristotle, is not brought out, and, in general, it is Aristotle as he influenced later philosophy that Prof. Weber presents to his reader. In the statement that "the *matter* of Plato, Aristotle, and Plotinus is not the matter of the materialists, but what Schelling and Schopenhauer would call *will* or the will-to-be," the suggestiveness is, in part at least, that of a *suggestio falsi*.

In his treatment of Kant, too, Prof. Weber has the after-development so vividly before him that the exegesis of the first *Critique* is somewhat injuriously affected. "Prior or *à priori* to" is, as Prof. Weber uses it, an incorrect phrase. The distinction between image and schema is lost by loose terminology. And, as is perhaps natural, the Refutation of Idealism is slurred as nonessential. Indeed the issue, as between Kant and Berkeley, is not understood; and it is significant that in the account of the latter the *Siris* is not mentioned. Berkeley, that is to say, is labelled idealist and a precursor of Hume, and his own intellectual development has no account taken of it. Another notable omission in the modern period is in the case of Lotze, who is just named and dismissed.

On the other hand, the scholastic period, which has devoted to it a larger proportion of space than is usual, is covered with some success, Prof. Weber's theological and ethical interests giving life to the inquiry. Anselm is admirably handled.

The translation is from the fifth French edition of the Strassburg Professor's book. The American translator has added in notes and appendix an adequate bibliography, without criticism, and with a not unnatural preference for transatlantic editions and translations.

Many of Prof. Wundt's metaphysical views were familiar to the world even prior to the appearance of his "System" so long ago as in 1889; and to offer an appreciation in detail of a well-known work by so great a teacher would be at once an impertinence and an anachronism. In welcoming, however, the second revised and slightly enlarged edition of the "System," it is perhaps permissible to recall some of its characteristics.

Prof. Wundt's idea of a philosophical system is a connected view of existence which shall satisfy both the demands of the understanding and the needs of feeling. It must be strictly *meta*-physical, after and based upon the experiential sciences. Its method may be described, perhaps, as a criticism of working categories, passing from conceptions of the understanding to the transcendent ideas and finding, as the end of the *Regressus* in each limited field, an inadequate point of view which needs supplementing, until we reach our Ontology. The basis of this is Will. But Prof. Wundt can as little accept what he calls Universal Voluntarism as he can the *intellectus infinitus*. Will, without something to will or without a relation of interaction in which to realise itself, is void, abstract, and not will as we know it. The solution of the problem he finds in a system of relatively independent wills in whose interaction ideas (*Vorstellungen*) arise. The principle of unity lies in the moral ideal of humanity. Collective will is a reality, but not in the sense of the school which derives from Schopenhauer.

Prof. Wundt is more happy, however, in his criticism of particular categories. His treatment of purposiveness in organic evolution is quite masterly, though he attaches somewhat too much importance to what he calls *Heterogonie* of ends. In this edition he refers specially to the controversy between Prof. Weismann and his critics in its most recent form, and declares definitely in favour of use-inheritance, though he draws a distinction between the suddenly acquired qualities of an individual and the gradually acquired characters which have become ingrain by like response to like stimulus repeated from generation to generation. He notes with some candour that it might in theory be maintained that the latter are transmitted because they alone are able to affect the germ-plasm. We do not venture to deal with Prof. Wundt's *Holoplasma* and its relation to the views of Nägeli.

The book stills lacks an index, a deficiency specially annoying since the same and allied subjects are taken up under more than one heading. H. W. B.

THE CORAL REEFS OF SAMOA.

Ueber den Bau der Korallenriffe und die Planktonvertheilung an den Samoanischen Küsten nebst vergleichenden Bemerkungen. By Dr. Augustin Krämer. With an appendix "Ueber den Palolowurm," by Dr. A. Collin. 8vo. Pp. ix + 174. (Kiel and Leipzig: Lipsius and Fischer, 1897.)

DANA'S main contribution to the Darwinian theory of coral reefs was a persuasive argument based on the geographical distribution and varying size of atolls and reef-grounds. Darwin had shown that if his theory were true, its most important corollary was that certain lines across the Pacific Ocean were lines of subsidence, and that others are either rising or stationary. Dana pointed out that as we approach the supposed lines of subsidence the areas of the coral reefs diminish, islands of non-calcareous rocks disappear, and the coral islands all become atolls, which gradually contract in size; after this comes a tract of sea without islands, and of great depth. Then, the axis of subsidence having been passed, small atolls reappear, the reverse series of changes occurs, until we reach an area of broad fringing reefs round some rocky island. Dana's most striking illustration of this method of reef distribution was the archipelago of Samoa, in which he described a gradual

passage from the westernmost, rocky island of Savaii eastward, past reefs of diminishing size, to the last member of the group, the small Rose Atoll. Beyond that island there are some 900 miles of open sea, until the small atolls of the Society Islands begin another series leading up to the great Paumotu Archipelago. Dana explained the distribution of the reefs by assuming that the line between Rose Atoll and the Paumotus had rapidly subsided. This suggestion was in harmony with all the known facts. It has been the argument least shaken during the discussion on Dr. Murray's theory, and has accordingly kept some men firm in the Darwinian faith. Funafuti was originally recommended by the original Coral Island Boring Committee as a suitable site for bore-hole, after it had been tested by this principle in order to minimise the chance of stumbling on an area of rising sea-floor.

Now, however, Dr. Krämer, in a detailed description of the Samoan reefs, shows that the facts are not exactly as stated, and that another explanation is available. Dr. Krämer's book opens with a sketch of the literature on the coral reef controversy, which is neither complete nor altogether accurate; for he numbers Admiral Wharton among the defenders of Darwin's theory, and Prof. Sollas among its opponents. He then gives an account of the topography, meteorology and geology of the Samoan group, after which follows a detailed description of the coral reefs. The next section of the book discusses the conditions which determine the limits of coral-reef formation, and in which the most original remarks are those dealing with the influence of heliotropism. (His observations on heliotropism in corals have, by the by, an important bearing on the question of the validity of coral species founded on the nature of the corallum.) He concludes his contribution to the reef controversy by a chapter entitled "a new view of the origin of atolls." Dr. Krämer points out, during his description of the Samoan reefs, that they are not disposed exactly as they should be to agree with Dana's suggestion, that the eastern end of the archipelago is undergoing rapid subsidence. The reefs are not as regularly arranged as has been thought. Proceeding from west to east, Savaii has no very extensive reefs except on the east coast; Upolu, the next island, has large fringing reefs at the west end, fringing and small barrier reefs in the middle section, and unimportant fringing reefs at the east end; Tutuila has only a fringing reef on the southern shore, and two submarine barrier reefs further out; Manua has no important reefs; finally, the easternmost island of the chain is Rose Atoll. These facts appear conclusive that the Dana argument will not hold for its typical locality.

Krämer then proceeds to discuss the origin of the remarkable shapes of atolls, which Darwin thought it was impossible to explain on the view that atolls formed either on the rims of volcanic craters or on submerged banks. Krämer invokes the aid of great geyser eruptions, in order to widen the bases and alter the forms of submarine volcanoes. He points out that the distribution of volcanic ejectamenta depends not only on its specific gravity, for ocean currents and tides carry the material and pile it up in the dead water to the lee of volcanic islands. He reproduces a chart from Dana, showing how the trend of the coral archipelagoes agrees with that of the ocean currents in their neighbourhood; and he supports this by similar charts of the Paumutu and Marshall Islands. The difficulty of deep lagoons he explains by assuming that atolls with such, originated on crater rims; and he is more inclined to Murray's solution theory than are most writers on coral islands, although he remarks that it does not seem sufficient by itself.

The concluding section of Dr. Krämer's book deals with some biological problems of the Pacific Ocean. A few pages are devoted to the reef fauna, considered in reference to its ethnological relations, and then follows a longer account of the Plankton. The author describes his apparatus and methods at some length. The most interesting result given in this section of the book are his statistics of the comparative poverty of the tropical Plankton compared with that of the temperate zones. In an appendix on the Palolo, a worm largely eaten by the Samoans, Tonguese and Fijians, Dr. Collin re-describes its structure from excellent material collected by Dr. Krämer. He agrees with Quatrefages and Ehlers that it is a member of the genus *Lysidice*, and that Gray's genus, *Palola*, must be given up. J. W. G.

OUR BOOK SHELF.

A Treatise on Practical Plane and Solid Geometry. By T. J. Evans and W. W. F. Pullen. Pp. vi + 400. (London: Chapman and Hall, Ltd., 1897.)

IN these 400 pages the joint authors present the student, particularly the one who wishes to restrict his work to the Science and Art Department syllabus of the honours stage of the annual examination held in geometry, with the solutions of a series of problems arranged in an orderly and progressive manner. The problems are, for the most part, those which have been set at the examinations held during the years 1887 to 1896, and their solutions are accompanied, in many cases, by useful hints. There are also included the theories of isometric projection, shadows, and perspective, and several interesting miscellaneous examples, besides some of the less difficult problems which are of fundamental importance. It is not advisable for a student to limit himself entirely to the reading of such a book as this, but using it in connection with a good text-book its value will be very much enhanced: for this reason, the authors have made ample references to existing standard works. No less important are the excellent and clearly printed figures, to the number of 200, which accompany the text; these should be well studied, and, in most cases, re-drawn by the reader himself. For advanced students and teachers this collection of problems and proofs will, without doubt, prove a most useful help in their work.

Les Transformateurs de tension à courants alternatifs. By F. Loppé. Pp. 206. (Paris: Gauthier-Villars. Masson and Co.)

Électromoteurs et leurs Applications. By G. Dumont. Pp. 183. (Same publishers.)

Électro-métallurgie. By A. Minet. Pp. 195. (Same publishers.)

THESE books are the three latest additions to the well-known series published under the title of the Encyclopédie scientifique des Aide-Mémoire. All the volumes in the series have proved handy and serviceable to students of science and technology.

The first part of M. Loppé's work deals briefly with the theory of the transformer, and ideal conditions of construction; the second part is devoted to the classification of transformers, details of construction, the

description of principal types, and the determination of the dimensions of the various parts of a transformer required to satisfy specified conditions.

M. Dumont begins his volume with a short account of the various means used for the distribution of energy. He then deals successively with different kinds of continuous current and alternate current electromotors, the advantages and disadvantages of the two types, and systems of electrical transmission of power.

M. Minet's volume is one of four which it is proposed to publish on electrolysis and electro-chemistry. One will deal with theories of electrolysis; another with electro-chemistry; electro-metallurgy is the subject of the present volume; and electric furnaces and their applications will be treated in the fourth volume. The general laws of electrolysis are described in the introduction to the volume before us, then methods of working in the wet way, with electrolytes containing dissolved salts, and afterwards processes of electro-metallurgy in the dry way, which includes the electrolysis of substances brought to a fluid state by igneous fusion, and electro-thermic reductions.

Cheese and Cheese-making. By James Long and John Benson. Pp. viii + 150. (London: Chapman and Hall, 1896.)

THOUGH this little volume bears the names of two authors, they can hardly be regarded as collaborateurs. What was the origin of the book does not appear, for there is no preface or introduction. Mr. Long writes five chapters at the beginning and three at the end, whilst the intermediate chapters, four in number, are by Mr. Benson. Each author writes independently of the other, and their respective contributions might equally well have appeared as separate pamphlets. The volume, of course, suffers from this lack of cohesion. Mr. Long's chapters are devoted to the principles of cheese-making, the trade in foreign cheese, soft cheese manufacture, Gorgonzola and the varieties of blue or moulded cheese, other varieties of fancy cheese, the milk industry, the principles of butter-making, and creameries and factories. For a chatty or discursive account of the numerous varieties of foreign cheese it may be safe to consult the volume, but the details of manufacture are hardly given with sufficient precision to possess any value for purposes of instruction. Occasionally, too, Mr. Long is a little uncertain in his choice of words, as when he makes reference to districts "where the most luxurious crops are grown"—he no doubt had luxuriant crops in mind. Mr. Benson deals with the best methods of manufacturing Cheddar, Stilton, Cheshire, and Wensleydale cheeses respectively. More care has been bestowed upon this part of the work, which in the hands of an intelligent person might usefully be employed as a guide to the making of the four varieties of English cheese specified. Connoisseurs will agree with Mr. Benson "that a well-made Stilton stands without rival amongst the better-known varieties of cheeses." One disadvantage of the dual but not joint authorship is that there is considerable repetition. Another is that the volume has no index. So well known a continental cheese as the Gruyère seems to have escaped notice, though the Gervais, Bondon, and Coulommiers receive attention. There are no illustrations.

The Naturalist's Directory. Pp. 102. (London: L. Upcott Gill, 1897.)

IT would be interesting to know what the editor of this book means by a naturalist, for we should then be better able to understand why most people whom we regard as naturalists do not appear in his list. The title-page informs us that the book is intended "for the use of students of natural history, and collectors of zoological, botanical, or geological specimens, giving the names and addresses of British and Foreign naturalists, natural history agents, societies and field clubs, museums, magazines, &c." But we have looked in the list for the names of about twenty well-known naturalists, and have not found one of them included. Perhaps the Directory only contains the names of amateur naturalists, or of naturalists inviting exchanges or correspondence?

In "a list of the principal natural history work published during 1896 in the British Isles," we notice a work on metallurgy, and several on chemistry. If these are branches of natural history, then the editor, to be consistent, should include chemists and metallurgists in the Directory.

Flowering Plants. By Mrs. Arthur Bell (N. D'Anvers). Pp. 204. Illustrated. (London: George Philip and Son.)

THOUGH this book is said to be "complete in itself," it it is not a sufficient guide to the beginner in botany, for the first chapter begins with the supposition that another volume has been read, and the meanings of such terms as "calyx," "corolla," "stamens," "pistil" are regarded as part of the mental stock-in-trade of the reader. The book has been written to introduce the reader in an easy and pleasant way to the common flowering plants; but though we read, on p. 157, "You can easily find either the common or the ivy-leaved Toad-flax for yourselves," we search in vain for any description sufficient to enable a young reader to recognise this plant. Most of the illustrations are reproductions of photographs. A few of them are good, but they are usually quite inadequate to enable the learner to identify specimens of the plants he will meet during his country walks.

Twelve Charts of the Tidal Streams near the Channel Islands and Neighbouring French Coast. By F. Howard Collins. (London: J. D. Potter, 1897.)

THESE charts show by arrows the tidal streams around the Channel Islands and as far as the neighbouring coast of France, when it is high water at St. Peter's Port, Guernsey; one, two, three, four and five hours after high water at that port; and six, five, four, three, two, and one hour before high water there. Hence, knowing the time at which high water occurs at St. Peter's Port on any particular day, the direction of the tidal streams in the neighbourhood covered by the charts at any time before or after high water can be seen. The charts are based upon Admiralty observations, and should be of service to yachtsmen in the Channel.

Guide to the Genera and Classification of the North American Orthoptera found North of Mexico. By Samuel Hubbard Scudder. Pp. 87. (Cambridge, Mass.: Edward W. Wheeler, 1897.)

THE tables and bibliographies contained in this book will prove very serviceable to students of Orthoptera in America. All the seven families of Orthoptera are found in the United States, but a large amount of work remains to be done upon them, and this volume will assist in the collection and study of material required for advancement. The author states that he "contemplates a general work on the classification of our Orthoptera, of which this is merely a Prodromus, and which may serve its purpose until the material at hand has been more thoroughly studied."

Aids to the Study of Bacteriology. By T. H. Pearmain and C. G. Moor, M.A. Pp. 159. (London: Baillière, Tindall, and Cox.)

A GOOD general idea of the science of bacteriology, especially in its pathogenic aspects, can be derived from this little book. As an introduction to the "Applied Bacteriology" of the same authors, the book should be welcomed by medical students and by all practitioners who wish to know something of the methods of bacteriological research, and to understand the significance of the results obtained.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On a Method of reproducing Astronomical Photographs.

PROF. MAX WÖLF, in his excellent article on the "Reflector and Portrait Lens in Celestial Photography," published in your issue of April 22 last, mentions a method of "reproducing nebulous masses" from original negatives, and refers to my reproduction of a photograph of the nebula M.8, done in collaboration with Mr. Lunt.

I have since tried the method on a number of other clusters and nebulæ with uniform success.

My practice now is to use a very slow plate capable of giving good contrast, and to give it the least possible exposure during contact-printing from the original negative. I use the ordinary Pyro-ammonia developer with half of the normal quantity of ammonia indicated, and with an excess of bromide. If there is the slightest indication of an image within five minutes, the plate is rejected as too much exposed. The development is continued for about forty-five minutes, with an occasional addition of a little more ammonia; the plate is, of course, kept rocking all the time in the dark. From the positive thus obtained a second negative is secured, and from it a second positive, and from the last a third negative, which is used for final printing on paper. The method of development is throughout the same as mentioned above.

Faint details in outlying portions, for instance, in the photographs of the corona can be very easily brought out in this manner.

No intensification by mercury or otherwise is employed by me, and I consider it absolutely inadmissible, as it is liable to affect the grains in the neighbourhood of the image, and thus to give a false extension of nebulous matter. The pure process of successive copying and bringing out contrast is perfectly legitimate; Scheiner and others having shown that the image does not spread thereby.

I beg to forward for your inspection the original negatives and reproduced copies of M.8 and the Orion nebula, and shall be glad if you can make use of them. K. D. NAEGAMVALA.

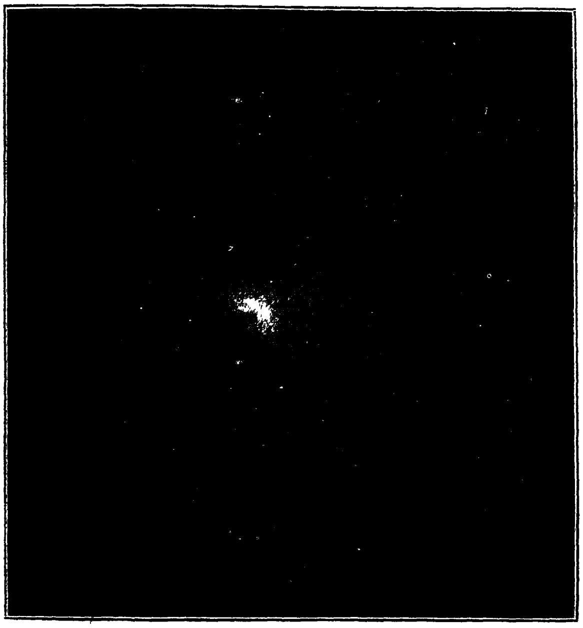
THE GREAT NEBULA IN ORION.



Original negative.

Negative twice re-copied.

On Mimicry.

DURING the discussion on Mimicry at the last meeting of the Entomological Society, the fact that so many mimetic species are scarce, in comparison with the non-mimetic allies and the models, was brought forward as an argument against the efficiency of mimetic resemblance. Amongst the Indo-Australian Papilios this phenomenon is strikingly illustrated by *Papilio alcidinus* and *caunus*, which resemble their models to a surprising degree. As both these rare species deviate widely from their nearest relatives, it occurs to me that the theory of Mimicry, which says that Homœochromatism and Homœomorphism between imitating and imitated species are the outcome of *selection*, can give a satisfactory explanation of the scarcity of individuals of mimetic forms. If we concede for the sake of argument that, for instance, *Papilio alcidinus* has acquired that wonderful similarity in colour and form to its model, an Uraniid moth, in consequence of a continued selection in the one direction, it is obvious that the result of such a one-sided selection will not only be similarity to the immune model, but also physiological one-sidedness. The more rigorous the selection is, the better will the mimetic species become adapted to its model, and the more will it lose its adaptability to new biological factors. Therefore, when changes in the biological conditions of the area inhabited by the mimetic form take place, such ever-occurring changes as have been described by Wallace in "Natural Selection," the mimetic species, best adapted in one direction, will be at a disadvantage to its relatives which have not been subjected to rigorous, one-sided selection. Consequently, the most striking "mimics," in spite of, or rather in consequence of, the resemblance to immune species, are, in the long run, the less favoured in the struggle for existence, which means that they will become relatively scarce. From this consideration it is apparent to me that the selection of those specimens which are the very fittest in any *special* direction is in itself a danger to the species, and can lead to destruction. The peculiar bearing which this suggestion has on the theory of Natural Selection, especially on the principle of utility, is evident.

Zoological Museum, Tring, June 7. KARL JORDAN.

Immunity from Mosquito Bites.

THE note of your correspondent (NATURE, No. 1438), relative to the above subject, leads me to point out that my own experience is the counterpart of that there presented. More than twenty years ago, as a young man, I camped during the months of May and June in the forest which bordered the south shore of Lake Superior, a region teeming with varied forms of insect-life, among which the mosquito held a conspicuous although not the most obnoxious place. I had previously been very sensitive to mosquito stings, and suffered acutely from them during the entire period spent in camp, my hands and face being so closely covered with the peculiar hard lumps resulting from the sting, that they presented in place of soft flesh only a series of contiguous swellings.

The temporary discomfort thus occasioned has since been abundantly recompensed. For many years afterwards mosquitos displayed a marked antipathy towards my blood, rarely stinging me if any other person were available as a subject for their attacks. This kind of immunity I have now partially lost, but even to the present time a mosquito sting occasions me very little annoyance. It is followed by no swelling, and the pain ceases within a few moments after the proboscis is withdrawn. GEO. C. COMSTOCK.

Washburn Observatory, Madison, Wis., U.S.A.

Sound Signals in Fog.

REFERRING to one of your Notes on page 130, I will take the opportunity of repeating a suggestion which I have several times made privately, viz. to have on board ship not a double emitter but a double receiver of sound:—a pair of trumpet-mouths or collectors or ears, one at each side of the ship, with the bulk of the ship as a shadow-throwing object between (like the head), and with tubes leading from them into the the captain's or other quiet cabin. The listen-out-man, having these tubes in his ears, would be able to hear distant sounds and estimate their direction with greater precision than if he trusted to his own small collecting organs, but I apprehend in just the same sort of way, and almost without training.

June 12. OLIVER J. LODGE.

Fire-fly Light.

IN answer to Prof. Silvanus Thompson's inquiry in NATURE of June 10, it may be stated that the "Johanniskäfer," or "Johanniswürmchen," is the common glow-worm, *Lampyris noctiluca*, L., or *Lampyris splendidula*, L. E. OVERTON.

Zürich, June 12.

THE APPROACHING TOTAL ECLIPSE OF THE SUN.

I.

THE failure of so many of the eclipse parties last year to secure observations, makes it a matter of congratulation that the weather prospects of the eclipse to be observed in India on January 22 next year seem to be as favourable as they possibly can be. I propose in the present article to refer generally to the objects to be attained, and to give an account of the proposed arrangements so far as I know them; and to show how fair the prospect of success this time is, I will begin by referring to a note drawn up by Mr. Eliot, F.R.S. Meteorological Reporter to the Government of India, in order to give the chief meteorological features of the tract of country in India through which the line of totality will pass.

The note begins by giving a general idea of the Indian climate.

"It may be premised that the year in India may be divided into two seasons or periods—the north-east or dry monsoon (or season), and the south-west or wet monsoon. During the south-west monsoon winds of oceanic origin prevail, and the whole of the period is one of frequent rain over the greater part of India. The chief features of this period, lasting from June to December, are moderately high temperature, moderate diurnal range of temperature, high humidity, much cloud, and more or less frequent rain. The amount of cloud and rain differ very considerably in different parts of the country, depending upon their position with respect to the neighbouring seas and the mountain ranges in India, and other conditions. The south-west monsoon winds usually withdraw from Northern India in September or October, and from the Bay of Bengal and Southern India in December. Hence the months of November and December form a transition period from the conditions of the wet to the dry monsoon, the change commencing in Upper India, and extending slowly eastwards and southwards.

"During the dry or north-east monsoon (extending from January to May), winds of land origin prevail in the interior of India. In Northern India these land winds blow down the larger river valleys, and are hence westerly over the Gangetic plain, the largest river plain in India.

"The first two months, January and February, form the cool weather of Northern and Central India and the Deccan. The mean temperature of the day ranges between an average of 71° in the Deccan (Berar, the Central Provinces, and Hyderabad), and 54° in the Punjab. The diurnal range of temperature is large in amount, varying between 25° to 35° or 40° in the interior. The air is usually very dry, skies free from cloud, and winds light, more especially in the Punjab and more remote districts of the interior. The disturbances of this period are feeble cyclonic storms of large extent, which cross Northern India from west to east, and give much cloud and light, to moderate rain in the plains and hills of Northern India. Temperature increases rapidly in March, and that month and the two following months of April and May form the hot weather season. The intensity of the hot weather conditions increases from March to May. The chief features of the weather of this period in the interior of India are high day temperature, large diurnal range of temperature, great dryness of the air, and strong day winds which raise clouds of dust, and more or less obscure the sky and sun. Cyclonic storms of large extent are of comparatively rare occurrence in this period. On the other hand, small local hot weather storms—including hailstorms, thunderstorms, and duststorms—are of frequent occurrence, and tornadoes are of occasional occurrence, in Bengal chiefly."

It follows from this sketch that the eclipse will occur in the middle of the cold weather and at the most favourable time of the year for travelling in India. Light north-east winds, fine weather, and smooth sea are to be expected. Cyclonic storms are of exceedingly rare occurrence in either sea during the month, and the chance of a gale or of stormy weather in the month off the coast of the Konkan (from Bombay to Karwar) is, according to Mr. Eliot, less than 1/50. He states:—

"The weather is throughout the month of January almost uniformly fine, with clear or lightly-clouded skies over the whole of the Peninsula. Light north-easterly to easterly winds obtain in the Deccan, or interior of the Peninsula. The west coast districts are protected by the West Ghats from these winds, and light land and sea breezes prevail. The most remarkable feature of the meteorology of the coast area from Bombay south to Karwar in January is the freedom of the skies from cloud. Disturbances are of very rare occcurence, and fine weather is hence almost a certainty during the whole of the month. There is, however, usually much dust in the air, raised by the dry winds in the Deccan."

Among other most important matter in Mr. Eliot's note is a table showing average temperature, humidity, cloud and rainfall data in January at certain stations in India near the line of totality. We gather that the mean temperature of the month of January in the Konkan coast districts is 76°, with a diurnal range of 20°. In the Deccan (*i.e.* at Sholapur, &c.) and the Central Provinces the mean temperature of the day in January is approximately 70°, and the diurnal range nearly 30°. In Bihar the mean daily temperature of the month is 62°, and the diurnal range 23°.

Mr. Eliot points out that since the air is very dry over the interior, and the mean daily humidity percentages at stations in the Deccan, Central Provinces, and Berar averages about 40°, any instruments brought out from Europe, such as photographic cameras, &c., should be constructed to withstand the action of this great dryness

of the air. With regard to cloud, the data show that the coast districts between Karwar and Ratnagiri (which includes the line of totality) is on the mean of the month more free from cloud than any other part of the line of totality.

"The amount of cloud is practically uniform in amount over the Deccan and Central Provinces, and is slightly greater in Bihar than in the Deccan or Central Provinces. The amount of cloud is very large at Darjeeling in January, and mist or fog almost invariably forms after clear nights in the morning (about 9 or 10 a.m.), and prevails more or less steadily until late in the afternoon, when it gradually disappears."

Rain is of rare occurrence during the month of January in the Konkan and Deccan. Its probability increases in proceeding from west to east. In the Konkan the average number of rainy days in the month is only 0·2, and in the eastern districts of the North-western Provinces the average number is 2, and in Bihar 1·2.

"The probability of a rainy day in January is hence about six times as great in Bihar as in the Konkan in January. The probability of any given day in January being rainy in the Konkan is less than 1/150, and in Bihar 1/25."

Mr. Eliot remarks, in connection with this, that skies are usually remarkably clear after rain in the Gangetic plain, and the atmospheric conditions for astronomical observations are at such times much finer than are ever obtainable in the Konkan or Deccan.

The local astronomical conditions at three points along the line of totality are thus stated in the "local particulars" issued from the Nautical Almanac Office. Local mean times and the points of contact for direct image are given.

The Joint Committee of the Royal and Royal Astronomical Societies have determined to send out three parties to observe, one on the coast and two inland, at stations to be subsequently decided upon. It has been arranged that the party from the Solar Physics Observatory will occupy the coast station if the Admiralty can

grant the use of a man-of-war to allow an attempt to be made to repeat the *Volage* programme of 1896.

In this case the station will possibly be the old fort at Viziadurg, for which point the following astronomical conditions hold, according to the Superintendent of the Nautical Almanac (Fig. 2).

Assuming the position of Viziadurg to be 16° 32′ N., and 73° 22′ E., the times of contact are (local mean time) :—

	d.	h.	m.	s.	
1898.—January	21	23	12	20	
,,	22	0	46	9	$P_2 = 241°$
,,	22	0	48	14	$P_3 = 51°$
,,	22	2	14	33	

These times are 4h. 53m. 28s. in advance of Greenwich.

The land parties—which will include the Astronomer Royal, Prof. Turner and Mr. Newall, representing the Observatories of Greenwich, Oxford and Cambridge, together with Dr. Common and Captain Hills—will occupy stations near the central line on the railways shown on the map (Fig. 1).

With regard to the work to be attempted by the coast party, to which I propose to confine myself in what follows, I may state, in the first place, that I am one of

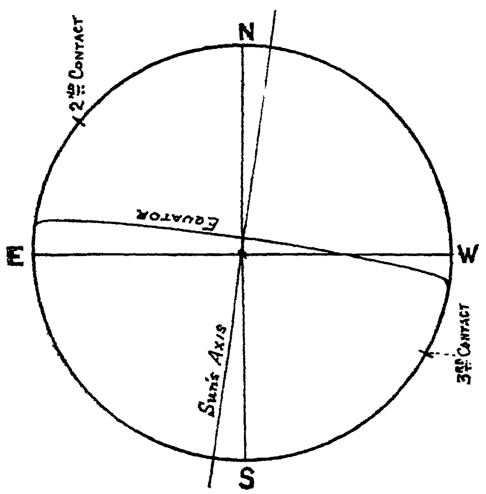

FIG. 2.—The conditions of observation at Viziadurg.

those who believe that spectroscopic observations during eclipses must take precedence of all others in the minds of students of solar physics; but when I say this, it must not be forgotten that other inquiries remain which are much more simply carried out, and are within the competence of those unacquainted with the details of the subject; one of the fortunate things about eclipses is that photographers and amateurs can do good work as well as those more fully equipped.

But to return to the spectroscope—What form of spectroscope are we to employ?

The Prismatic Camera.

Fraunhofer, at the beginning of the century, found that in order to observe the spectra of stars the best thing to do was to put a prism outside a telescope, and to let the light enter the telescope and be brought to a focus after it had passed through the prism; and it is a most unfortunate thing, that the neglect of the application of this principle has landed us probably in a delay of fifteen or twenty years in gathering knowledge on this subject. Now the spectroscopes with which most are familiar are armed with a slit through which the light to be examined is made to enter, and the rays are next rendered parallel before they enter the prism in a part of the instrument called the collimator. After passing the prism they are again collected to a focus by means of a telescope.

But a spectroscope need not be so complicated as this, for after all the object of the instrument is to disperse white light as we see it dispersed in a rainbow, and what nature accomplishes by a rain-drop we can do by a prism; hence, if we simply pass a ray of white light through a prism, we find that after it has so passed through, it is changed into a beautiful band, showing all the colours of the rainbow. This prism then is the fundamental part of the instrument, and the most complicated spectroscope which we can imagine simply utilises the part which the prism plays in breaking up a beam of white light into its constituent parts from the red to the violet. Between these colours we get that string of orange yellow, green, and blue, which we are familiar with in the rainbow. For sixpence any of us may make for ourselves an instrument which will serve the purpose of demonstrating many important spectroscopic results. From an optician we can get a small glass prism for sixpence; glue it at one end of a piece of wood about $12 \times 1 \times \frac{1}{2}$ inch, so that we can see through it a coloured image of a needle stuck in at the other end of the piece

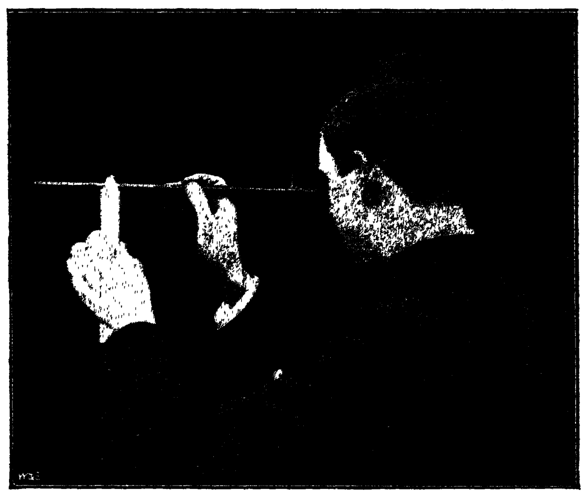

FIG. 3.—A simple form of spectroscope.

of wood (Fig. 3). This we must do by looking sideways through it.

Allow the needle to be illuminated by the flame of a spirit lamp into which salt is gradually allowed to fall. We see an image of the needle coloured in orange. If we next illuminate the needle by a candle or gas flame, taking care that the direct light from the candle does not fall upon the face of the prism, we then get no longer a single image of the needle, but a complete band of colour from red to blue. We have, in fact, an innumerable multitude of images of the needle close together.

It will be clear from these experiments that in our *impromptu* spectroscope we see simply images of the needle, few or many, according as the kind of light we are studying contains few or many differently coloured rays.

In the more complicated instrument we pass from an illuminated needle to a fine straight slit through which light is allowed to enter. We generally talk of "line" spectra for the reason that a narrow slit is employed, the image of which is a line. In the "lines" seen in the spectra of the heavenly bodies we have so many celestial hieroglyphics which we have to translate into chemical

language by comparing their positions with those we observe in the spectra of terrestrial light sources.

But a straight slit is not the only kind of aperture we can employ; we may replace it by a ring, for instance.

What we shall see in passing from the spectrum of a candle to the spectrum of a spirit-lamp flame with salt in it, using first a straight and then a circular slit, is shown in the accompanying woodcut (Fig. 4).

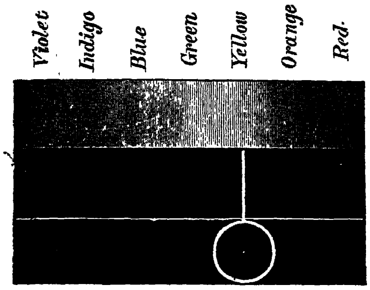

FIG. 4.—The spectra of continuous and discontinuous light sources, the latter seen with a line and circular slit.

If we examine a very complicated light source we shall arrive at the same result, a spectrum characterised by a large number of bright circles or lines (Fig. 5).

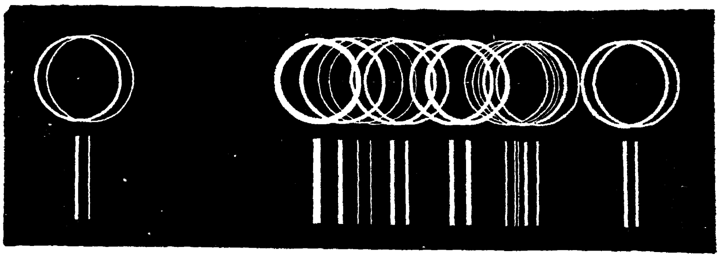

FIG. 5.—The spectrum of a complicated light-source as seen with a circular and a line slit.

FIG. 6.—Details of objective prism.

We have seen that in an ordinary spectroscope, when we are studying light sources close to us, the rays have to be made parallel before they pass through the prism. But the heavenly bodies are at such a distance from us that their light reaches us in a parallel beam, so that one part of the spectroscope, the collimator, may be dispensed with. A star as a point is part of a line slit; hence the success of Fraunhofer's arrangement for observing stellar spectra, to which I have referred. In an eclipse we get a bright narrow ring round the dark moon. There is our ring slit. Hence the so-called "slitless spectroscope," or "prismatic camera," as it is called when photography is employed, used to study the spectra of stars and the sun's chromosphere during eclipses.

The way in which, in the prismatic camera, the prism is fixed outside the object-glass, is shown in the accompanying figure (Fig. 6).

We are now in a position to inquire how this arrangement has been used during eclipses since 1871. J. NORMAN LOCKYER.

(*To be continued.*)

THE OLD RED SANDSTONE OF LORNE.

THE terraced hills of Lorne, though a familiar feature in the scenery of western Argyllshire, have not yet had their geology properly worked out. Their peculiar topography, however, has long been known to arise from the outcrops of successive sheets of lava, lying upon and intercalated with strata of purple shale and conglomerate. The age of these strata has never been satisfactorily settled. For many years past I have regarded them as probably belonging to the Lower Old Red Sandstone, for their lithological characters present a close resemblance to those of the great basin of that age in central Scotland, which I have distinguished by the name of "Lake Caledonia." While recently mapping in the district, Mr. R. G. Symes, of the Geological Survey, came upon an exposure of the sedimentary rocks, which seemed to him so promising a locality for fossils that he requested the assistance of one of the fossil-collectors of the staff with a view to more minute examination. Accordingly, Mr. A. Macconochie was detailed for the purpose, and was soon rewarded by the discovery of undoubted remains of plants and fishes. The specimens were first sent to the Office of the Survey in Edinburgh, where the plants were recognised by Mr. B. N. Peach as portions of *Psilophyton*, and the fish-remains as parts of *Cephalaspis*. His identification of the ichthyolites was immediately confirmed by Dr. R. H. Traquair. The specimens were then forwarded to the Jermyn Street Museum, where they have been again examined by Mr. E. T. Newton, who entirely agrees with the opinion already pronounced regarding them.

The occurrence of a genus of plants and another of fishes so characteristic of the Lower Old Red Sandstone

of central Scotland is of singular interest and importance, for it definitely fixes the geological age of the volcanic series of western Argyllshire and its accompanying sedimentary deposits. ARCH. GEIKIE.

INTERNATIONAL CONGRESS ON TECHNICAL EDUCATION.

THE International Congress on Technical Education, referred to in last week's NATURE, was opened on Tuesday, at the rooms of the Society of Arts, under the presidency of the Duke of Devonshire. The meeting of the Congress in London is due to this Society, and to the City Companies, which guaranteed the necessary expenditure.

The subject of higher technical education claims the attention of all who are concerned with the progress of science and the development of arts and industries. The pressing importance of the question is indicated by the article which appears in another part of this number. We take it that the scheme of Prof. Klein, to establish an educational system which will bring theory and practice more closely together, is the ideal organisation. The man of science and the engineer should be one; for both need to understand the practical aspects of nature, and both are constantly inventing methods of investigation. Prof. Klein wishes to give life to fossilised Universities, and lead them "so to develop science that the results will be practically useful, and repay the debt to engineers which science now owes them." This aim, coming from one who has enriched mathematics with so many remarkable contributions, should do much to break down the supposed barrier between the investigator working in his laboratory and the engineer working towards the mastery of nature on a larger scale. For the details of the scheme, we refer our readers to the article in another place. To our mind, the plan proposed will do much to advance higher technical education; and it will perhaps lead to the development of teachers who are good mathematicians as well as practical men. In all countries there are signs of increasing interest in methods of education, so that Prof. Klein's views will doubtless receive consideration outside Germany.

In opening the International Congress, the Duke of Devonshire pointed out that each country could learn much from the experience and organisation of others. It is for this reason that such Congresses have a beneficial effect. In the course of his address, the Duke of Devonshire is also reported by the *Times* to have made the following remarks :—

It is in a double capacity that I have the honour of offering a welcome to the International Congress on Technical Education. We have in this country a Department of Education, but its functions are almost entirely limited to elementary education, and we have not in our Administration any Minister who properly corresponds to the Minister of Education of other Governments. Nevertheless, the President of the Council is the Minister on whom the nearest approach to responsibility for education rests, and the Vice-President, Sir John Gorst—who, I trust, will take part in the future proceedings of the congress —is the Minister who, representing the Government on educational matters in the House of Commons, shares with the President a large part of his responsibility. It is, therefore, partly in our official capacity that Sir John Gorst and I take part in these proceedings. The comparatively unorganised condition of education as a whole has led to the formation of unofficial and irresponsible associations to promote and help to organise special branches of education to meet the growing needs of the country. Turning to the business of the congress, its previous assemblies have done much to increase public interest in the very important question of technical instruction; and the well-arranged and representative programme of the present assembly justifies the hope that its deliberations on the present occasion will be no less fruitful than in the past. The present time is well chosen for an international congress on technical instruction. In all countries there are signs of increasing interest in foreign methods of education. Systems of education, indeed, cannot be transferred ready-made from one country to another. Education is a thing too closely interwoven with national life and habits to permit any such easy transference. But when every allowance has been made for this it remains true that each country can learn very much from the experience and the educational organisation of other countries. Educational ideas and ideals may be communicated, although systems of administration cannot be transferred without great modification and adjustment to special circumstances; we find therefore that in point of fact English education has been materially affected during the last sixty years by waves of foreign influence coming in succession from France, Holland, Germany, Switzerland, America, and Scandinavia. And in some respects there is no department of education in which methods of teaching and plans of organisation can be more readily transferred from one country to another than is the case in technical instruction, which is the subject of the present congress. In many respects this country has been the debtor in this long process of foreign educational exchange. But there is one point at least in which continental critics are now paying Great Britain the compliment of careful study and even of admiration. The need for individual initiative and for freedom of local experiment has always been fully recognised in English education, and in no grade of it has this been more the case than in technical instruction. While the central Government, through its administrative departments, has not failed to give a certain measure of guidance to the new movement, it has thrown the greater part of the responsibility on the local authorities, believing that (in technical education especially) there must be great elasticity in administration and incessant adaptation of the means and form of instruction to meet the great variety of the industrial and commercial needs which exist in the different localities, but can only be ascertained and fully tested by local experiment. The local authorities have, with few exceptions, risen to their new responsibilities with an alacrity and enterprise which deserve high commendation. All of those who are labouring for the extension and improvement of technical instruction in Great Britain, as well as in Ireland, where a remarkable movement is now in progress for the furtherance of technical education, will learn much from the reports brought by the foreign delegates. They will also take special interest in the accounts to be given by distinguished visitors of technical education in Canada, in India, and in Australia. To British hearers probably no part of the discussions will be more instructive than that which is to be devoted to the subject of commercial education. In the field of higher commercial education, Great Britain is believed by many competent observers to be seriously behind several of the continental nations. Attention would also be usefully directed to the influence of Germany, and especially the Realschulen of Berlin, in producing, by means of a carefully planned modern secondary education, given by trained teachers of the highest attainments, an increasing number of youths eminently fitted to profit by the highest kinds of technical education, and to promote the commercial interests of their country.

Papers chiefly relating to different aspects of the teaching of chemistry were then read and discussed.

ALVAN G. CLARK.

A NOTE of extreme sadness is mingled with the congratulations that have followed the completion of the Yerkes telescope. Hardly is the object-glass in its cell, and before the final adjustments can possibly be complete, the intelligence comes that the artist, who has laboured so earnestly and so successfully in the work of figuring object-glasses of the largest size, is struck down suddenly by apoplexy. Ten years ago, Alvan Clark, the founder of the firm, died, after completing the lens of the Lick telescope, but before he could witness its complete installation and be assured of its final success. The son, Alvan G. Clark, was probably aware of the excellence of the Yerkes telescope, both from his own experience and the certificate of Prof. Keeler; but he, too, is denied the pleasure of seeing it used under the most favourable conditions, and of hearing expressed the full satisfaction of those astronomers in whose hands the telescope is placed.

It is impossible to disconnect the life of Alvan G.

Clark from that of the firm with which he was associated throughout his life. It would be ungenerous to deny him his share in the success that has attended the use of such astronomical triumphs as the Washington telescope, the Pulkova, or the Lick, because they were completed in his father's lifetime. His practical participation in the work of the firm as far back as 1862, is attested by his discovery of the companion of Sirius in the course of the optical trials to which he was submitting the first large telescope the firm had constructed. Here his capacity to use a telescope is shown as effectually as he afterwards demonstrated his power to make one, and though the opportune discovery may have done much to strengthen the reputation of the firm, it did not tempt him to join the ranks of astronomical observers in preference to those of the practical optician. Possessed with the tradition of the workshop, and inheritor of his father's skill and experience, he has been content to supply the means for others to use, and in this way has rendered no mean service to astronomical science. None of those who have won an acknowledged position for accurate or for delicate work by means of the instruments the famous house of A. Clark and Sons has placed in their hands, would deny the obligation they are under to those who have devoted themselves freely and unselfishly to secure the best that art can devise, or skill and patience execute. In precisely the same manner Mr. Clark would acknowledge his indebtedness to those who have supplied him with the glass, out of which he has constructed those lenses, wherewith he has broken the record of all previous efforts in the same direction. The house of Feil, among others, has rendered him the same kind of service that he has rendered to astronomy—services that are not covered by a mere monetary payment. When we hear of the discovery of some minute speck of light, and admire the skill and dexterity of manipulation of the astronomer who has added another fact to the history of observational astronomy, it is well to remember all the causes that have contributed to his success, not to rob him of his deserved popularity and reputation, but to remind ourselves of the intimate connection pervading many branches of science and industry.

We have alluded to some of the large telescopes in which the reputation of the son is worthily joined with that of the father. We may recall another, the Bruce photographic telescope, whose successful figuring rests entirely with the younger Clark. Here the difficulty of construction was much increased by the fact that the final focal length of the combination was agreed upon between the contracting parties, and that very considerable accuracy was demanded in maintaining the original agreement. Mr. Clark triumphed over all difficulties, we believe, to the complete satisfaction of Prof. Pickering, and, if we correctly understood Mr. Clark, without the assistance of the method of "pilot" glasses or small objectives, constructed of similar glass and of like curves to those intended to be used in the construction of the finished lenses.

America has lost, perhaps, her ablest practical optician. Others starting with his experience and assisted by a lavish generosity will no doubt in time surpass his masterpieces; but his loss is a great one, and at this particular juncture will be keenly felt in the new Chicago Observatory.

NOTES.

THE sum of 297,000 francs has been subscribed for the Pasteur statue which is to be erected in Paris. M. Falguières has been commissioned to design the statue.

AT the meeting of the Paris Academy of Sciences last week, it was announced that subscriptions amounting to twenty-five thousand francs had been collected in Russia towards the fun for the erection of a statue of Lavoisier, and that this sum had been forwarded to the Academy.

THE International Postal Union has decided that natural history specimens and objects for scientific collections, shall be regarded as samples, and charged at the rate of a halfpenny for every two ounces.

WE learn from the *Bulletin* of the Botanical Society of France that it is intended to recognise in perpetuity the services rendered to viticulture in France by the late botanists, M. P. Duchartre and M. F. Laforgue, by placing commemorative marble plates on the houses where they were born, both in the neighbourhood of Béziers.

IT is stated in *Science* that Miss Catherine W. Bruce, of New York City, has again shown her great interest in astronomy by sending Prof. J. K. Rees, Director of the Columbia University Observatory, a cheque for fifteen hundred dollars. The money is to be used in publishing the observations and reductions for "Variation of Latitude and the Constant of Aberration," made by Profs. Rees and Jacoby and Dr. Davis.

DR. G. SANARELLI delivered a lecture at Montevideo on Thursday last, upon the etiology and pathogenesis of yellow fever, with special reference to the yellow fever bacillus discovered by him (see NATURE, February 18, vol. lv. p. 370). There was a very large attendance at the lecture, including a number of scientific delegates from all parts of South America, the members of the Diplomatic Body, and the principal authorities. Dr. Sanarelli confirmed his previous announcement that the cause of yellow fever is a bacillus named by him icteroid, which is rarely found either in the blood of yellow fever patients or in their bodies after death, because it easily disappears. Dr. Sanarelli said that he would shortly make experiments in preventive vaccination, and hoped to discover a curative serum.

THE Council of the Royal Society of Edinburgh have awarded the following prizes:—The Gunning Victoria Jubilee Prize for 1893-96 to Mr. John Aitken, for his brilliant investigations in physics, especially in connection with the formation and condensation of aqueous vapour; the Keith Prize for 1893-95 to Dr. Cargill G. Knott, for his papers on the strains produced by magnetism in iron and in nickel; the Mackdougall-Brisbane Prize for 1892-95 to Prof. John G. M'Kendrick, for numerous physiological papers, especially in connection with sound; the Neill Prize for 1892-95 to Mr. Robert Irvine, for his papers on the action of organisms in the secretion of carbonate of lime and silica, and on the solution of these substances in organic juices. The prizes will be presented by Lord Kelvin at the last meeting of the session, July 5.

WE regret to announce the following deaths:—Dr. Matthew Charteris, professor of materia medica in Glasgow University; Mr. Alvan Clark, the well-known manufacturer of lenses for telescopes; Prof. Dr. R. Fresenius, the distinguished chemist; Mr. Ney Elias, who won the gold medal of the Royal Geographical Society about twenty-five years ago, for his journey from Pekin to St. Petersburg, and since then explored a part of the desert of Gobi, and traversed the Pamirs; Rev. Alexander Freeman, a Fellow of the Royal Astronomical, Mathematical, and Physical Societies, and deputy for the Plumian Professor of Astronomy at Cambridge in 1880-82; the distinguished Austrian metallurgist, Prof. Peter von Tunner, at the age of eighty-nine. In 1875 he was elected an honorary member of the Iron and Steel Institute, and in 1878 received from that society the Bessemer Gold Medal in recognition of his important discoveries connected with the metallurgy of steel.

A VERY severe shock of earthquake was felt at Calcutta, at 5 o'clock last Saturday afternoon, June 12. It is stated that, from first to last, the disturbances continued for fully five minutes. Few houses escaped damage of some description, and many are in ruins. Many church towers and spires collapsed, and most of the public buildings were badly damaged by the disturbances. Reuter's agency reports that the area affected by the earthquake was very extensive. Telegrams received from Simla, Agra, Bombay, Manipur, and from places far down in the Central Provinces, report that a shock was felt almost at the same time as the earthquake occurred at Calcutta. The shock appears even to have left its record on seismometers on this side of the earth. Prof. Milne obtained at Newport, Isle of Wight, on Saturday morning, a seismographic diagram of an earthquake of unusual magnitude. It began at about 11.30 a.m., and lasted three hours. Further, a Reuter telegram from Paris states that the seismograph at Grenoble registered an earth tremor at 11.28 on Saturday morning. Both these records evidently refer o the Calcutta earthquake.

PRESIDENT MCKINLEY has transmitted to the Senate the report on forestry made by the Committee of the National Academy of Sciences at the request of the Secretary of the Interior. The following general scheme of administration of forest preserves is submitted:—A forestry bureau under a director, who is to be president of an advisory board, consisting of himself, an assistant director, and four forest inspectors. It also provides that the bureau shall have a disbursing officer, clerks, and legal advisers; twenty-six head foresters, twenty-six assistants, to constitute a permanent corps; two hundred rangers and various assistant rangers, the salary roll calling for an annual appropriation of 250,000 dollars, with preference of appointment to West Point graduates. The Legislature of the State of New York at its recent session granted one million dollars for the purchase of forest preserves in the Adirondachs; and a surveyor has just been appointed to survey the lands about Indian Lake, in order to acquire them for the State under this Act.

THE great anthropological expedition sent out by President Morris K. Jesup, of the American Museum of Natural History, left New York for British Columbia a few days ago, in charge of Dr. Franz Boas, curator of the anthropological section of the museum. His associate, Mr. Harland J. Smith, preceded him, and Dr. Livingstone Farrand, of Columbia University, accompanies him. The headquarters of the expedition will be situated in British Columbia, where about thirty Indian dialects are spoken. The language and habits of the Indians will be carefully studied, and elaborate anthropometrical observations made. Mr. Smith will engage in archæological researches in the southern portion of the territory, and several other parties will be scattered throughout British Columbia. An expedition to Alaska is contemplated for next spring; also, at some time in the near future, an expedition to Southern Siberia. All this work is under the general supervision of Prof. F. W. Putnam, though he will not take the field in person, at least for the present; the field work being under the direction of Dr. Boas.

IT has been briefly announced that next year Captain Sverdrup proposes to take the *Fram* up Smith Sound to the north-west coast of Greenland for the purpose of prosecuting exploration in that direction. Though Dr. Nansen will not accompany the expedition, the *Times* states that there is reason to believe that he is taking an active share in the direction of the expedition. The object will be to penetrate north through Smith Sound and Robeson Channel as far north as possible along the north-west coast of Greenland. An attempt will be made to discover how far Greenland extends northward, and to survey the north-west, north, and north-east coasts. In short, one prime object will be to complete the exploration of the Greenland coast, a considerable extent of which is still quite unknown.

LIEUT. PEARY has been detached from duty at the Brooklyn Navy Yard, and granted five years' leave of absence in order to enable him to prosecute his Arctic researches. He expects to begin the first trip on July 10, sailing from Boston, and will be away three or four months. Prof. C. H. Hitchcock, of Amherst, and Prof. Geo. H. Barton, of the Massachusetts Institute of Technology, will accompany him, and also probably a party from Yale. The route will be from Boston to Sydney, U.S., thence through the Gulf of St. Lawrence and the Belle Isle Straits to Resolution Island and the Greenland coast, then along the coast 1200 miles to Melville Bay. The scientific parties will be landed on the way, and picked up by the ship on its return trip in September. The main object of this trip is to prepare for a longer one of three or four years to be undertaken next year, and to attempt to reach the Pole by gradual approaches, and colonising Eskimos in high latitudes. Lieut. Peary states that he is assured of funds sufficient to prosecute the work for five years if need be, but the name of the donor is withheld. The scheme, however, has the endorsement of the American Geographical Society and the American Museum of Natural History.

THE results of a preliminary study of the conditions which exist in highly rarefied media under discharges of electricity are described, by Prof. John Trowbridge, in a paper entitled "The Energy Conditions necessary to produce the Röntgen Rays" (*Proc. Amer. Acad. of Arts and Sciences*, vol. xxxii. No. 14, April 1897). It appears from the experiments "that the discharge in a Crookes' tube, when on the point of emitting the Röntgen rays most intensely, is an oscillatory one, and that each discharge encounters a resistance less than five ohms. An estimate of the great amount of energy thus developed in an exceedingly small interval of time can be obtained if we suppose that Ohm's law holds for individual oscillations. This reservation is an important one, for the investigations I have described in this paper show that a discharge of six inches in length encounters no more resistance during its oscillations than one of two inches in length. In popular language, it can be maintained that a discharge of lightning a mile long encounters no more resistance than one of a foot in length. Ohm's law does not hold good for electrical discharges in air and rarefied gases. It is well known that a voltaic arc can be started in a vacuum. My experiments lead me to believe that in every case the arc is started by a spark which breaks down the medium, and the arc follows. I am led to believe that electrical oscillations are of the nature of voltaic arcs, and that the discharges in Crookes' tubes are voltaic arcs. I am thus forced to the conclusion that under high electrical stress the ether breaks down and becomes a good conductor."

DR. H. H. HILDEBRANDSSON, Director of the Meteorological Observatory at Upsala, has recently communicated to the Royal Swedish Society of Sciences the results of an important investigation upon the "Centres of action of the atmosphere," or the regions at which are situated the mean barometric maxima and minima. The monthly differences of the pressure of the air from the mean, as being the principal meteorological element, were calculated for the years 1875–84 at sixty-eight stations, distributed as widely as possible over the surface of the globe; the mean differences were then plotted upon monthly charts. The results obtained from the lines of equal differences show: (1) That the differences are greater in winter than in summer, and increase from the equator towards the polar regions, and also that the barometrical variations at certain localities, *e.g.* at the Azores and in the vicinity of Iceland, are

almost always opposite in sign, especially when the figures are large. (2) That the greatest differences are found in January and July in the vicinity of Greenland and Iceland on the one hand, and to the north of Russia, between the White Sea and St. Peter burg, on the other. The discussion seems to establish the fact that a kind of oscillation exists at all places in the pressure of the air between a centre of action of high pressure and another adjacent centre of low pressure. The author states that a closer study of these relations promises to lead to practical results for the prediction of weather for long periods.

THE current number of the *Annales de l'Institut Pasteur* contains M. Pottevin's annual report for 1896 on the anti-rabic inoculations conducted during the past year at the Paris Pasteur Institute. The number of persons treated was 1308, less than in any previous year since the Institute was opened. This diminution is attributable to the fact that patients, instead of going to Paris from all parts of the country, undergo the inoculations at the institutes now established at Lille and Marseilles; also similar institutes have been founded in Algiers and Turin, districts which formerly sent considerable numbers of cases to Paris. During the ten years which have elapsed since the opening of the Paris Institute, 18,645 persons have been treated there, and an interesting table is appended showing the nationality of the patients, from which it appears that England contributed no less than 870 individuals, and more than any other country; Belgium coming next, with 429. In some of the departments of France cases of rabies have steadily diminished, thanks to the energetic measures taken by the local authorities; whilst in others, where less vigorous steps have been taken to guard against its dissemination, the number of cases has increased. It is in the southern districts of France that, M. Pottevin tells us, "possess the sad distinction of containing the largest number of bitten persons, and of paying the most dearly for disobedience to the laws of the sanitary police."

IN north latitude 70° 40′ 11″·3, where the most northerly town in the world—namely, Hammerfest—is situated, there is a monument which was visited by most of those who went to Norway to obtain a view of the total solar eclipse. This monument consists of a fine granite pedestal and pillar supporting a large terrestrial globe made of copper, and was placed there to commemorate the completion of a grand piece of surveying work. The primary object of this survey was, as Mr. Fowler writes in an interesting article in *Knowledge* (June), the measurement of the earth, and to provide a permanent mark in order that the measurements may be repeated at any future time if considered desirable. Without entering into the details of a trigonometrical survey, and how a triangulation is accomplished, we will limit ourselves to the inscription, written in Latin and Norwegian, on the pillar, referring the reader to the article in question for details. "The northern termination of the arc of meridian of 25° 20′ from the Arctic Ocean to the river Danube, through Norway, Sweden and Russia, which, according to the orders of His Majesty King Oscar I., and the Emperors Alexander I. and Nicholas I., and by uninterrupted labours from 1816 to 1852, was measured by the geometers of the three nations."

PROF. P. TACCHINI, of Rome (*Atti dei Lincei*, vi. 9), describes a remarkable thunderstorm which passed over Italy on April 24, in which the rain was mixed with sand and seeds of the *caroub* that had evidently been transported from Africa.

IN a preliminary note published in the *Rendiconto della R. Accademia delle Scienze fisiche e Matematiche* (Naples), Dr. R. V. Matteucci and Dr. E. Giustiniani announce the discovery for the first time of the element selenium among the products of the "fumaroli" of Vesuvius. Dr. Matteucci has also completed a brief but accurate investigation of the dynamical phenomena connected with the eruption of 1895, of which he gives an account in the same journal.

FROM a series of investigations on the effect of cutaneous excitations on the formation of red blood-corpuscles, Prof. H. Kronecker and Dr. A. Marti, writing in the *Atti dei Lincei*, draw the following conclusions: (1) Feeble irritations of the skin promote the formation of red blood-corpuscles, but modify the formation of hæmoglobin in different ways. (2) Strong irritations of the skin determine a diminution of the number of red corpuscles, and, in a minor degree, of the hæmoglobin contained in the blood. (3) Darkness diminishes the number of blood-cells; after about a fortnight, a minimum is reached which is followed by a limited increase. (4) Continued exposure to intense light (even at night with electric light) induces the formation of red blood corpuscles, and also, in a lesser degree, of hæmoglobin.

A RÖNTGEN Society has been formed, with Prof. S. P. Thompson as the president. The intention of the founders is that the Society shall occupy a position between those devoted purely to medicine, to physics, or to photography. Some of the members will study the sources of the Röntgen rays, others the applications; some the induction coils, others the tubes and the various forms and adaptations of the apparatus used in the production of the rays. Röntgen photography has been found serviceable in so many branches of scientific investigation that the Society appeals to a large constituency for support. It should be the means of increasing the efficiency and applications of the rays, and should also be of assistance to surgeons and others who have entered the new field of work without previous training in physics.

To the June number of the *Strand Magazine*, and also to *McClure's Magazine*, Prof. S. P. Langley contributes an interesting illustrated narrative of his experiments with flying machines, and the development of the aerodrome to the condition in which it was able to demonstrate the possibility of mechanical flight. A description of the aerodome was given by Prof. Langley in these columns a year ago (vol. liv. p. 80, May 28, 1896), and the first successful flight of the machine was then described by Mr. Alexander Graham Bell.

ANOTHER name must be added to the long list of martyrs who have given up their lives while endeavouring to effect the conquest of the air. The latest victim is Dr. Wölfert, who had devoted many years to the problem of aerial navigation, and who claimed to have invented a navigable balloon. The Berlin correspondent of the *Times* says that Dr. Wölfert had made an arrangement with the officers of the ballooning section of the army to put his invention to a practical test at Tempelhof on Saturday last. The officers and a number of persons interested in aerial navigation assembled to witness the ascent. The balloon was of the new cigar-shaped form. The car was a square basket made of bamboo cane, and contained a benzene motor of eight-horse power, partly constructed of aluminium, and driving at one end of the car a propeller of the same material. At the other end of the car was a so-called helm, consisting of bamboo staves covered with linen sails. The balloon had already been tested on several occasions, and was said to have attained a very high rate of speed against the wind. Dr. Wölfert was accompanied in his ascent by a mechanic named Knabe. At first the balloon ascended steadily and began to make good progress against the wind in the direction of the suburb of Rixdorf, to reach which and to return to Tempelhof was the task set himself by its inventor. Suddenly, however, when the balloon was sailing at a height of about 1000 feet, flames shot up from the car and the balloon exploded with a loud report and was precipitated, a burning mass, into a wood-yard below. The

mounted officers hurried to the spot, and, after the flames had with great difficulty been partially extinguished, the mutilated remains of Dr. Wölfert and his companion were found amidst the ruins of the car. It is believed that the valve of the balloon was opened with the intention of descending, and that the gas, in escaping from the balloon, became ignited by the benzene.

ALL who work for the advancement of natural knowledge have reason to be grateful to the Smithsonian Institution. Under the administration of this renowned organisation come the U.S. National Museum, the Bureau of Ethnology, the Bureau of International Exchanges, the National Zoological Park, and the Astro-physical Observatory—all of which have largely contributed to the progress of science. By the exchange service the operations of the Institution extend almost to the ends of the world. How immense this branch of the work now is may be gathered from the fact that more than 24,000 correspondents are upon the exchange lists, about eleven thousand being establishments and thirteen thousand individuals. The correspondents are distributed in nearly four thousand different places, from Disco, Greenland, in north latitude 70°, to Port Stanley, Falkland Islands, in latitude 50° S.; and they extend east and west so as practically to embrace the earth. The distribution of the correspondents is indeed proportional to the spread of civilisation, and the educational status of Spain as compared with France, or China in comparison with Japan, can be rightly inferred from their relationships with the Smithsonian Institution alone.

ANOTHER work for which the Smithsonian Institute deserves the gratitude of men of science is the general appendix now printed with the Report of the Secretary. This appendix preserves for us year by year a number of very valuable papers, covering a considerable range of scientific investigation and discussion. The collection of carefully selected contributions usually contains the most important and interesting articles and addresses which were published during the year covered by the Report in which they are included. The volume just received contains thirty contributions of this character, gathered from the published literature of 1895. There are several papers which won prizes or commendation in the Hodgkins Prize Fund competition; addresses delivered at the Ipswich meeting of the British Association by Prof. W. A. Herdman and Mr. W. T. Thiselton-Dyer; a translation of a discourse by Prof. W. Ludwig von Graff on "Zoology since Darwin," and other translations from German and French journals; several papers on American archæology; a translation of the address delivered by the late M. Jules Simon at the centenary celebration of the Institute of France; a paper on science in early England by Mr. C. L. Barnes; a paper on the plan of research in education, contributed to *Science Progress*, by Dr. H. E. Armstrong; and a memorial address on Huxley, by Prof. Theodore Gill. These are but a few of the subjects of the reprinted publications; but they suffice to show the comprehensive character of the collection, and will serve to call attention to a veritable storehouse of information.

"THE ELECTRICIAN" Company are about to issue a work by Mr. W. Clark Fisher on the "Potentiometer and its Adjuncts," being a description of a universal system of electrical measurement.

MR. A. W. BENNETT has been appointed by the Council of the Royal Microscopical Society editor of the Journal of the Society, in succession to Prof. F. J. Bell.

THE Geological and Natural History Survey of the Chicago Academy of Sciences has issued its first "Bulletin," consisting of a monograph of the Lichen-flora of Chicago and its vicinity, by Mr. W. W. Calkins.

M. J. CARDOT (Stenay, Meuse, France) is about to publish a catalogue of all the species and varieties of *Sphagnum* or bog-moss, with the synonymy and geographical distribution of each species and variety. It will comprise 215 species, nearly 600 varieties, and more than 500 synonyms.

A TYPE-HERBARIUM of Lichens and a lichenological library have been instituted at Chambésy, near Geneva, under the direction of the curator of the Herbier Boissier. In memory of a late distinguished lichenologist, it will be known as the "Salle Müller-Aargau."

MESSRS. WHITTAKER AND CO. will shortly publish a volume on "Organic Chemical Manipulation," by Dr. J. T. Hewitt. The first part of the book will give an account of the methods adopted in organic analysis and the determinations of molecular weight, the second part being devoted to a typical set of organic preparations, systematically arranged and intended to give an idea of the methods adopted in organic work.

THREE publications from three of our public schools have been received during the past few days. From Harrow School has come the second volume of "Harrow Butterflies and Moths," by J. L. Bonhote and Hon. N. C. Rothschild. The first volume of this praiseworthy work has already been noticed in NATURE (vol. lii. p. 388). The present volume includes the Macro-lepidoptera not described in the former volume, and eight of the Pterophoridæ recorded from the Harrow district. The locality, time of appearance, and distinguishing features of the different species are noted; so that the volume will prove of service to collectors, as well as a record of permanent value to entomological science.—The Rugby Natural History Society have just issued their report for 1896. The papers printed in the report are on the Macro-lepidoptera of Hertfordshire, from personal observation, by H. W. Blathwayt; Lichens, by R. A. Worthington; the Aboriginals of Australia, by C. Ansted; and Photomicrography, by K. Lucas. We are glad that the Society is able to give evidence of its vitality; for we regard the expeditions made by the members, and the encouragement given to individual observation, as of the highest educational value.—The report of the Marlborough College Natural History Society is even more complete than that from Rugby. It contains papers by E. Meybrick, on the vertebrate animals (except birds) of the Marlborough District, the cretaceous fossils of the district, and botanical classification, and also a paper on acids, by R. G. Durrant. The Society appears to be in a very flourishing condition, and the reports of the various sections testifies to commendable enthusiasm of the members. A particularly interesting feature is the anthropological report containing statistics of weights and measurements of members of the school.

THE additions to the Zoological Society's Gardens during the past week include two American Flying Squirrels (*Sciuropterus volucella*) from North America, presented by Miss Lucy Sanderson; a Grey Squirrel (*Sciurus griseus*) from North America, presented by Mr. D. S. Millar; fourteen Common Chameleons (*Chamæleon vulgaris*) from Egypt, presented by Dixon Bey; two Eyed Lizards (*Lacerta ocellata*) from Southern Europe, presented respectively by Lieut.-Colonel Willoughby Verner and Mr. G. K. Gude; three Common Squirrels (*Sciurus vulgaris*), British; an Eroded Cinixys (*Cinixys erosa*) from West Africa, purchased; four Humboldt's Penguins (*Spheniscus humboldti*) from Western America, received in exchange; a Thar (*Capra jemlaica*, ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

NEW SOUTHERN VARIABLE STARS.—During the past few years Prof. Kapteyn has been obtaining the negatives for the Cape Photographic *Durchmusterung*, but, owing to great pressure of work at the observatory, a minute examination of the plates could only until quite recently be made. As a result of such a search several new variable stars have been discovered; and if this examination had been commenced earlier, there is little doubt that five other variables discovered independently would have been credited to the Cape Observatory. The list of new variables now published by Dr. Gill (*Astr. Nachr.*, 3426) includes four well-marked variables, their positions for 1875 and magnitudes being given in the following table. The range of magnitude, as given by the plates examined, is shown in the third column.

α (1875·0) h. m. s.	δ (1875·0) ° ′	Range of magnitude.	
4 50 56	−21 24·9	9·25— 9·8	Nov. '95 and Feb. '96
8 41 3	−50 6·4	9·6 —10·0	Jan.–April '96
9 28 41	−36 3·8	8·8 — 8·9	May 14, 28, '90
		8·7 — 9·6	Feb. 22, 24, and March 7, '96
12 2 55	−44 43·7	8·95 – 9·75	March '96

The same communication also refers to stars of the 9th magnitude, or brighter, which are contained in the Cordova *Durchmusterung*, but are missing, or barely visible, in the Cape plates. The variability of five other stars has in this way been established.

THE 1897 MAXIMUM OF MIRA CETI.—Prof. J. A. C. Oudemans communicates a paper by Dr. Nyland, of Utrecht, who carefully observed the variable Mira Ceti from August 5, 1896, to March 10, 1897, although as he states the weather restricted his observations to a great extent. On the whole, however, the observations were fairly distributed over this period, with the result that a very good curve could be drawn through the points when laid out on millimetre paper. The curve which is included in the communication (*Astr. Nachr.*, No. 3426) indicates that on September 2, 1896, this star was at its minimum brightness, 8·50 mag.; while on January 11, 1897, it had risen to a maximum, namely 3·70 mag. These magnitudes would correspond to 8·8 and 3·5 on the scales of Schönfeld and Argelander. This further stated that the magnitude at this period of maximum was very small, in fact among the fourteen observed maxima in the years 1840-1859 only one was observed (1847 November 16) that was dimmer than that of 1897.

COMET DENNING 1894 I.—Prof. Schulhof compares (*Bulletin Astronomique*, Tome xiv. p. 168) the observed places of this comet with those given by the ephemerides. Using his second system of elliptic elements (*Astr. Nachr.*, No. 3231) he finds that the corrections to the ephemerides is very considerable for the five last observations made at Nice. He has then employed his third system of elements (*Astr. Nachr.*, No. 3236) for the representation of these observations, but still this does not reduce the differences very considerably. Prof. Schulhof finally formed his five normal places and represented them by the fourth system of elements (*Astr. Nachr.*. No. 3276.) In this way he formed a table giving the corrections to be applied to the provisional ephemerides and the deduced positions. The elements he finally uses are, as he says, probably a little nearer the truth than those of M. Lamp (*Astr. Nachr.*, 3278). With regard to the relation between Brorsen's Comet and that of the one in question, M. Lamp showed that the two comets on January 24, 1881, passed nearly simultaneously the same point in space where their orbits coincided, namely, $l=284° 27'$, b $6= -1° 46'$, $r=5·1827$, and both he and Mr. Hind have considered this comet of Denning's as a fragment of that of Brorsen. Prof. Schulhof does not, however, seem to think this hypothesis is confirmed. The elements of the two comets, he states, are too dissimilar to allow of such an assumption, π and Ω differing by 15°, and the inclination by nearly 24°. The two velocities at the period indicated above differed by as much as three kilometres per second, and such an increase in velocity, he states, is probably too large to be caused by the shock of an explosion.

OBSERVATIONS OF MARS.—The current number of the *Bulletin de la Société Astronomique de France* (June) is devoted mainly to observations of Mars made by several well-known observers. Mr. Percival Lowell records some curious observations of the Sea of Sablier, or Syrtis Major. This marking has always been looked upon as an expanse of water or a sea; but Mr. Lowell's recent observations seem to corroborate those of Prof. W. H. Pickering, who examined this spot with a polariscope, and could detect no sign of polarisation. He says that the Syrtis Major is neither an ocean, nor a sea, nor anything analogous, but something very different, namely, a large expanse of vegetation. The changes observed in this marking in 1896 seem, at any rate, to suggest such an explanation as offered by Mr. Lowell.

The other observations included are:—Mr. R. Patxot Jubert's, made at the Observatory of Sant Feliu de Guixols Gerona (Spain); Mr. José Comas Sola's, made at Barcelona; Mr. V. Cerulli's, made at Teramo (Italy); Mr. A.-A. Wonaszer's, made at Kis-Kartal; and MM. Flammarion's and Antoniadi's, made at the Observatory of Juvisy. M. Antoniadi gives also a map of the whole surface as seen by him during the opposition of 1896, and a comparison of this with charts made at other previous oppositions is of great interest. The observations made during 1896 indicate, on the whole, that great changes take place on the planet's surface. The question of vegetation and a small water supply seems, perhaps, to account for the observed facts more than any other hypothesis yet advanced, and this explanation is in conformity with rapid seasonal changes which have recently become so apparent.

SIGNALLING THROUGH SPACE WITHOUT WIRES.[1]

IN 1884 messages sent through insulated wires buried in iron pipes in the streets of London were read upon telephone circuits erected on poles above the housetops, 80 feet away. Ordinary telegraph circuits were found in 1885 to produce disturbances 2000 feet away. Distinct speech by telephone was carried on through one quarter of a mile, a distance that was increased to one and a quarter mile at a later date. Careful experiments were made in 1886 and 1887 to prove that these effects were due to pure electro-magnetic waves, and were entirely free from any earth-conduction. In 1892 distinct messages were sent across a portion of the Bristol Channel between Penarth and Flat Holm, a distance of 3·3 miles.

Early in 1895 the cable between Oban and the Isle of Mull broke down, and as no ship was available for repairing and restoring it, communication was established by utilising parallel wires on each side of the Channel and transmitting signals across this space by these electromagnetic waves.

In the electro-magnetic system two parallel circuits are established, one on each side of a channel or bank of a river, each circuit becoming successively the primary and secondary of an induction system, according to the direction in which the signals are being sent. Strong alternating or vibrating currents of electricity are transmitted in the first circuit so as to form signals, letters and words in Morse characters. The effects of the rise and fall of these currents are transmitted as electro-magnetic waves through the intervening space, and if the secondary circuit is so situated as to be washed by these ethereal waves, their energy is transformed into secondary currents in the second circuit which can be made to affect a telephone, and thus to reproduce the signals. Of course their intensity is much reduced, but still their presence has been detected though five miles of clear space have separated the two circuits.

Such effects have been known scientifically in the laboratory since the days of Faraday and of Henry, but it is only within the last few years that it has been possible to utilise them practically through considerable distances. This has been rendered possible through the introduction of the telephone.

In July last Mr. Marconi brought to England a new plan. My plan is based entirely on utilising electro-magnetic waves of very low frequency. It depends essentially on the rise and fall of *currents* in the primary wire. Mr. Marconi utilises electric or Hertzian waves of very high frequency, and they depend upon the rise and fall of electric force in a sphere or spheres. He has invented a new relay which, for sensitiveness and delicacy, exceeds all known electrical apparatus.

The peculiarity of Mr. Marconi's system is that, apart from the ordinary connecting wires of the apparatus, conductors of very moderate length only are needed, and even these can be dispensed with if reflectors are used.

[1] Abstract of a discourse delivered before the Royal Institution. June 4, by W. H. Preece, C.B., F.R.S.

The Transmitter.—His transmitter is Prof. Righi's form of Hertz's radiator.

Two spheres of *solid* brass, 4 inches in diameter, are fixed in an oil-tight case of insulating material, so that a hemisphere of each is exposed, the other hemisphere being immersed in a bath of vaseline oil. The use of oil has several advantages. It maintains the surfaces of the spheres electrically clean, avoiding the frequent polishing required by Hertz's exposed balls. It impresses on the waves excited by these spheres a uniform and constant form. It tends to reduce the wave-lengths—Righi's waves are measured in centimetres, while Hertz's were measured in metres. For these reasons the distance at which effects are produced is increased. Mr. Marconi uses generally waves of about 120 centimetres long. Two small spheres are fixed close to the large spheres and connected each to one end of the secondary circuit of the "induction coil," the primary circuit of which is excited by a battery, thrown in and out of circuit by the Morse key. Now, whenever the key is depressed sparks pass between the small and large spheres, and since the system formed by the large spheres contains capacity and electric inertia, oscillations are set up in it of extreme rapidity. The frequency of oscillation is probably about 250 millions per second.

The distance at which effects are produced with such rapid oscillations depends chiefly on the energy in the discharge that passes. A 6-inch spark coil has sufficed through the system of spheres up to four miles, but for greater distances we have used a more powerful coil—one emitting sparks 20 inches long. It may also be pointed out that this distance increases with the diameter of the large spheres, and it is nearly doubled by making the spheres solid instead of hollow.

The Receiver.—Marconi's relay consists of a small glass tube four centimetres long, into which two silver pole-pieces are tightly fitted, separated from each other by about half a millimetre—a thin space which is filled up by a mixture of fine nickel and silver filings, mixed with a trace of mercury. The tube is exhausted to a vacuum of 4 mm., and sealed. It forms part of a circuit containing a local cell and a sensitive telegraph relay. In its normal condition the metallic powder is virtually an insulator. The particles lie higgledy-piggledy, anyhow in disorder. They lightly touch each other in an irregular method, but when electric waves fall upon them, they are "polarised," order is installed. They are marshalled in serried ranks, they are subject to pressure—in fact, as Prof. Oliver Lodge expresses it, they "cohere"—electrical contact ensues, and a current passes. The electric resistance of Marconi's relay—that is, the resistance of the thin disc of loose powder—is practically infinite when it is in its normal or disordered condition. It is then, in fact, an insulator. This resistance drops sometimes to five ohms, when the absorption of the electric waves by it is intense It therefore becomes a conductor. It may be that we have in the measurement of the variable resistance of this instrument a means of determining the intensity of the energy falling upon it. This variation is being investigated both as regards the magnitude of the energy and the frequency of the incident waves. Now such electrical effects are well known. In 1866 Mr. S. A. Varley introduced a lightning protector constructed like the tube, but made of boxwood and containing powdered carbon. It was fixed as a shunt to the instrument to be protected. It acted well, but it was subject to this coherence, which rendered the cure more troublesome than the disease, and its use had to be abandoned. The same action is very common in granulated carbon microphones like Hunning's, and shaking has to be resorted to to decohere the carbon particles to their normal state. M. E. Branly (1890) showed that copper, aluminium and iron filings behaved in the same way. Prof. Oliver Lodge, who has done more than any one else in England to illustrate and popularise the work of Hertz and his followers, has given the name "coherer" to this form of apparatus. He has much improved it. Marconi "decoheres" by making the local current very rapidly vibrate a small hammer-head against the glass tube, which it does effectually, and in doing so makes such a sound that reading Morse characters is easy. The same current that decoheres can also record Morse signals on paper by ink. The exhausted tube has two wings which, by their size, tune the receiver to the transmitter. Choking coils prevent the energy escaping. Oscillations set up in the transmitter fall upon the receiver tuned in sympathy with it, coherence follows, currents are excited, and signals made.

In open clear spaces within sight of each other nothing more is wanted, but when obstacles intervene and great distances are in question height is needed; tall masts, kites, and balloons have been used. Excellent signals have been transmitted between Penarth and Brean Down, near Weston-super-Mare, across the Bristol Channel, a distance of nearly nine miles.

It is curious that hills and apparent obstructions fail to obstruct. The reason is probably the fact that the lines of force escape these hills. Weather seems to have no influence; rain, fogs, snow and wind, avail nothing.

There are some apparent anomalies that have developed themselves during the experiments. Mr. Marconi finds that his relay acts even when it is placed in a perfectly closed metallic box. This is the fact that has given rise to the rumour that he can blow up an ironclad ship. This might be true if he could plant his properly tuned receiver in the magazine of an enemy's ship. Many other funny things could be done if this were possible. I remember in my childhood that Captain Warner blew up a ship at a great distance off Brighton. How this was done was never known, for his secret died shortly afterwards with him. It certainly was not by means of Marconi's relay.

The distance to which signals have been sent is remarkable. On Salisbury Plain Mr. Marconi covered a distance of four miles. In the Bristol Channel this has been extended to over eight miles, and we have by no means reached the limit.

It is easy to transmit many messages in any direction at the same time. It is only necessary to tune the transmitters and receivers to the same frequency or "note." Enough has been done to prove its value, and to show that for shipping and lighthouse purposes it will be a great and valuable acquisition.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Mr. R. A. Buddicom, Scholar of Keble College, has been elected to the University Biological Scholarship at Naples.

The University, in view of the visit of so many distinguished men to England for the Diamond Jubilee celebrations, has decided to confer the honorary degree of D.C.L. on Her Majesty's Premiers, amongst others, at this year's Commemoration. The following will therefore be the recipients of this honour:—The Hon. W. Laurier, Premier of the Dominion of Canada; Hon. Sir W. V. Whiteway, K.C.M.G., Premier of Newfoundland; Hon. Sir J. Gordon Sprigg, K.C.M.G., Premier of Cape Colony; Hon. G. H. Reid, Premier of New South Wales; Hon. G. C. Kingston, Premier of South Australia; Hon. Sir H. M. Nelson, K.C.M.G., Premier of Queensland; Hon. G. D. Taubman-Goldie, K.C.M.G., Governor of the Royal Niger Company; and Mr. E. H. Godkin, of New York.

The Junior Scientific Club met on June 9 and 16. Papers were read by Mr. R. R. Marett (Exeter), on the sanctions of savage morality; and by Messrs. P. Elford (St. John's) and N. E. Moss (Trinity) on artificial silks; E. H. Hunt (Balliol) and A. S. Fisher (New College).

Convocation on Tuesday unanimously passed a decree conveying the cordial thanks of the University to the Worshipful Company of Drapers for their munificent offer to erect a new building for the Radcliffe Library at the expense of 15,000*l.*

CAMBRIDGE.—Prof. Fitzgerald, of Dublin, has been appointed an Examiner for the Adams Prize, in the place of the late Mr. E. J. Stone.

The Senior Wrangler is Mr. W. H. Austin, of Trinity. Six out of the first seven Wranglers are from the same College. In Part II. of the Tripos, Messrs. Barnes and Wilkinson, of Trinity (bracketed second, 1896), and Mr. Houston, of St. John's (bracketed fifth, 1896), are placed in the first division, the Senior Wrangler of last year being in the second division. No ladies are classed as Wranglers this year.

IT is stated in the *American Naturalist* that work will soon be in full progress on the erection of a portion of the new Museum of Archæology and Palæontology, for the University of Pennsylvania. A botanical garden, covering ten acres, will be laid out around the museum. The site of the structure was ceded to the University by the city on condition that a museum of art and science, surrounded by a botanical garden, be erected on it. The portion to be erected immediately will cost not less than 500,000 dols., while the cost of the whole building will amount to 4,000,000 dols.

THE following are among recent appointments:—Dr. J. Franz, Assistant Professor of Astronomy at Königsberg, to be Director of the Breslau Observatory, and Professor of Astronomy in the University there; Dr. Frech to be full Professor of Geology in the University of Breslau; Dr. Carl Paal to be full Professor of Pharmaceutical and Applied Chemistry in the University of Erlangen; Dr. Paul Samassa to be Associate Professor of Zoology in the University of Heidelberg; Dr. Bredt, of Bonn, to be full Professor of Chemistry in the Polytechnic Institute at Aix; Dr. E. B. Copeland to be Assistant Professor of Botany in the University of Indiana; Mr. William George Hibbins, Whitworth Exhibitioner, and Research Scholar of the Mason College, Birmingham, to be additional Assistant in the Mechanical Engineering Department of the Merchant Venturers' Technical College, Bristol.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 3.—"The Sensitiveness of the Retina to Light and Colour." By Captain W. de W. Abney, C.B., D.C.L., F.R.S. Received May 10, 1897.

The author treats first of the extinction of the sensation of light on the centre of the retina. He made his reduction of the intensity of the light falling on the illuminated spot with a new piece of apparatus, which consisted of a gelatine wedge bent so as to make an annulus. He describes this wedge and its graduation, showing how its readings can be utilised, they being proportional to the logarithm of the intensity of light passing through it.

It is found that the smaller the spot of illuminated surface, the less reduction in intensity of the light is required, and that the amount of reduction of the light falling on the spot which just produces no sensation of light, is connected with the size of the spot by a simple formula, $I = x^m$, where I is the intensity and x the diameter of the spot. Further, he finds that it is the smallest diameter which governs the necessary reduction in intensity, and not the area of the illuminated surface. Having experimented with the extinction of light at other parts of the retina, he finds that it obeys the same law. Since a large and a small area having the same actual illumination appear to be of different brightness, an investigation was made of the relative luminosities of the two, and it was found that the two were connected by a very simple law.

The reduction of the intensity of a coloured ray to extinguish all colour was next measured with areas of different dimensions, and it was shown that again the intensity of the reduced light was connected with the size of the spot by a simple expression similar to that of the extinction of all light, but the exponential coefficient differed, indicating that light and colour were not connected together in the manner which might be expected.

The author then deals with the question of colour fields, and finds that all colour fields are of the same form, the extent depending solely on the illumination and the area of the surface the image of which fails on the retina. He finds that there is a connection between the intensity of the colour and the extent of the field which can be expressed by a formula, as also can the connection between the size of the spot of illuminated surface and the extent of field. He gives the curves of illumination for equal colour fields, and the curves of extent of field for every colour in the prismatic spectrum. Finally he makes an investigation into the relative sensitiveness to light of various points in the retina, and shows that there are "iso-lumes," or fields of equal sensitiveness, which appear to be of the same form as the colour fields.

He points out that there are difficulties in reconciling these results with either the Young or Hering theory of colour vision, and suggests a modification in the accepted theory of light and colour which may explain the connection between the two.

"On the Nature of the Contagium of Rinderpest." By Alexander Edington, M.B., F.R.S.E., Director Colonial Bacteriological Institute, Cape Colony.

In the following paper it is proposed to communicate to the Royal Society the results of experiments made in South Africa on the infectivity of the blood of animals affected with rinderpest. The experiments were all made on cattle kept under conditions in which accidental spontaneous infection could with certainty be excluded. These experiments had been concluded in 1896, before the arrival of Dr. R. Koch in South Africa, and their results had been communicated to him on his arrival.

(1) The blood of an animal ill with rinderpest, when taken during the febrile stage or previous to death, and injected subcutaneously or intravenously into healthy cattle, produces the typical disease—rinderpest, provided the blood is prevented from coagulating.

(2) The onset of coagulation and actual coagulation of the blood exerts a marked destructive influence on the virulence of such blood.

(3) The best method of obtaining virulent blood is to draw it aseptically from the jugular vein of an animal ill with rinderpest, and to mix it immediately with a 1 per cent. solution of citrate of potash, the latter previously well sterilised, in the proportion of 2-3 parts of blood to 1 part of citrate of potash solution. Such blood, as has been shown, remains fluid.

(4) This citrate of potash mixture of blood proves virulent in the first few days, generally not exceeding six days; after six days' keeping the virulence becomes rapidly weakened, so that after nine days the blood mixture is altogether inert.

(5) Admixture of glycerine to citrate blood does not *cæteris paribus* interfere with the virulence of such blood. Glycerine added to fresh blood does interfere with the virulence of the latter on account of the coagulation of the blood.

(6) The nasal mucus of an infected animal when used fresh and rubbed into the nostrils of normal cattle, produced in all instances typical rinderpest. We have never had a single failure in attempting to produce the disease by this means. By keeping the nasal mucus, even for a few hours, its virulence becomes markedly less.

(7) The condition of marked swelling of the lymphatic glands is one of, if not indeed the most evident pathognomic feature of the disease. The contagium exists as a primary infection in the lymphatic glands.

(8) A very mild attack of rinderpest, such as is produced by injection of blood of greatly decreased virulence, does not convey absolute immunity, this latter being produced in proportion to the severity of the attack through which the animal had passed primarily. An animal seemingly affected may have a relapse of the disease, which may go on to fatal issue or be mild in type, leading to recovery. Animals in the latter case always acquire immunity of a high degree.

Physical Society, June 11.—Mr. Shelford Bidwell, President, in the chair.—A mathematical paper was read by Mr. C. S. Whitehead, on the effect of sea-water on induction telegraphy. If a secondary circuit containing a telephone is rightly placed with respect to the field of a primary circuit traversed by an alternating current, signals may be transmitted over considerable distances. The author investigates the effect of filling the intervening space with sea-water; and, generally, the effect of a spherical conducting shell on the induction, at a point in a dielectric, due to an alternating current in a circular circuit, when the axis of the conductor passes through the centre of the shell. In the mathematical treatment, two cases are considered. (1) To find the normal magnetic induction at any point in the dielectric outside the shell when a circular circuit carrying an alternating current is placed in the dielectric inside a spherical conducting shell. (2) To find the normal magnetic induction at any point on the remote side of an infinite conducting plate, due to a circular circuit parallel to the plate. In both cases the following result is arrived at:

$$\frac{v_0}{u_0} = e^{-q\eta}$$

where v_0 is the maximum value of the normal magnetic induction at any point outside; w_0 the maximum normal magnetic induction due to the current in the primary, supposing the conducting shell or plate absent, at the same point; η the thickness of the shell or plate; and

$$q = \left(\frac{2\pi\mu p}{\sigma}\right)^{\frac{1}{2}}$$

where μ is the permeability of the conducting shell or plate; σ its specific resistance, $p = 2\pi$ times the frequency. If the frequency is 300, $p = 1885$. For sea-water, σ is taken as 2×10^{10} C.G.S. units; and $\mu = 1$. The sea-depth at the North Sand Head corresponds to $\eta = 2000$ cms. Hence, in this case, $\frac{v_0}{u_0} = \cdot 21$, or 79 per cent. is lost. Similarly, when

$\eta = 1000$, the loss is 54 per cent. The method employed in the investigation is that suggested by Lamb and Niven; the author adds an expression for Ω, the solid angle subtended by the circuit at any point, in terms of Bessel's functions. Mr. Evershed referred to some experiments of his own, from which he concluded that the author's formula gave too low an estimate of the attenuation; the discrepancy indicated that some term had been neglected. Mr. Yule doubted whether the equations given by the author were quite applicable to sea-water. There was need, apparently, of a term involving the polarisation of the medium. Mr. Heaviside communicated a criticism of the paper. It was not necessary to investigate the problem for any particular form of circuit from which the waves proceed. The attenuating factor for plane waves, due to Maxwell, was sufficient. Taking the best-known value for the conductivity of sea-water, there was no reason why the conductivity should interfere with signalling. A considerably greater conductivity must be proved for sea-water before it could be accepted that the failure of experiments on telegraphic communication with light-ships from the sea-bottom was due to that factor. It was unlikely theoretically; and Mr. Stevenson had contradicted it from a practical standpoint. For some reason, the account of the light-ship experiments had not been published, so that there was no means of finding the real cause of failure.—Mr. T. H. Blakesley read a paper on a new definition of focal length, and an instrument for determining it. The author asserts the principle that the focal length of a lens-combination is an abstract quantity, not necessarily the distance between two particular points. It is a quantity best defined in terms of some function of the two distances of object and image from their appropriate focal centres. Such a function is the magnification factor, m, the linear ratio of image to object, positive if the image is erect with regard to the object. Consider a particular pair of conjugate foci on the axis of a lens-system. Let one of these foci be at distance v from some fixed point on the axis, measured positively, in the direction of the rays. Then $\frac{dv}{dm}$ is constant, and is the focal length, f. If v_0 is the value of v when $m=0$, $v-v_0=f.m$. Let u be the position of the other focus, and u_0 its value when $m=\infty$. Then $u-u_0=f.m^{-1}$; and $\frac{v-v_0}{u-u_0}=m^2$. The last expression, m^2, may be called the "areal magnification"; it is important in determining photographic exposure. The author describes an optical bank which enables $\frac{dv}{dm}$ to be measured by a very simple operation; it gives also a record, on a paper strip, of the magnification-factor corresponding to various relative positions of object and image. Dr. S. P. Thompson said the paper was the most important contribution to geometrical optics that had appeared for many years. The introduction of the magnification function was a most useful device leading to exceedingly simple results. The important thing to measure was not so much the focal length as the reciprocal of that quantity. Dr. Chree said the photographic method at present used at Kew for determinations of focal length gave greater security than any more direct method. The colour of the light had to be taken into account. Mr. Blakesley, in replying, called attention to the use of his strip diagrams of magnification, for enlarging purposes in photography. When the magnification along some definite line was known, the focussing-cloth might almost be dispensed with.—Dr. J. A. Fleming read a paper on a method of determining magnetic hysteresis loss in straight iron strips. The author's process is based upon the use of the bifilar reflecting watt-meter. The samples of iron, large or small, in the form of straight strips are inserted in a long solenoid. The solenoid is traversed by an alternating current, and the square-roots of the mean-square values of the current are determined by a Kelvin balance. A flat bobbin of fine wire may be slid along the strip; an electrostatic voltmeter connected to the ends of this exploring coil gives the square-roots of the mean-square values of the electromotive force in that coil. From these measurements and the known dimensions of the solenoid and coil, the induction density, B, can be found at any point of the length of the strip. From these results a curve is drawn, coordinating the values of B to corresponding distances along the half-length of the strip. Assuming the hysteresis loss per cycle, per c.c. of iron, to vary as the 1·6th power of the maximum induction density, and then raising all the B ordinates to the 1·6th power, and plotting a new curve over the first, another curve is obtained which represents the variation of hysteresis loss per c.c. of iron from point to point along the half-length of strip. Now, at some point along the half-length of strip there must be a section where the induction density is B, such that the true *mean* hysteresis loss for the *whole* bar is proportional to $B_1^{1·6}$. Let this value of the induction density be called the "*effective value*," and the corresponding point in the strip the "*effective point*." Let $M·B^{1·6}$ stand for the mean ordinate of the curve representing the varying values of $B^{1·6}$ all along the half-length. Then, evidently,

$$B_1 = \sqrt[1·6]{M·B^{1·6}}$$

The following curious experimental result is found. Whatever may be the length or section of the iron strip, the point at which the actual induction density has a value equal to the "effective" value, always comes at the same proportional distance from the centre of the strip. This distance is very exactly equal to 0·56 of the half-length, as measured from the middle; or 0·22 of the whole length from one end. If, therefore, the secondary coil is placed at that spot, and the secondary voltage then observed is used to calculate the induction density, the value so obtained corresponds to the true mean value of the varying hysteresis loss per c.c. all along the strip. Mr. Carter asked whether roots other than the 1·6th gave a similar constant value of the induction density. Dr. Fleming said it seemed to be the result of accident that the 1·6th root gave a constant value for iron.—The President proposed a vote of thanks to the authors, and the meeting adjourned until June 25.

Geological Society, May 26.—Dr. Henry Hicks, F.R.S., President, in the chair.—On augite-diorites with micropegmatite in Southern India, by Thomas H. Holland, Officiating Superintendent, Geological Survey of India. This paper dealt with a series of basic dykes intersecting the pyroxene-granulites and gneisses of the Madras Presidency, and believed to be of the same age as the lava-flows of the Cuddipah system. These dykes consist essentially of augite (near hedenbergite) and a plagioclase-felspar (near labradorite), between which we find masses of micropegmatitic intergrowths of felspar and quartz, with a micro-miarolitic structure. Around the patches of micropegmatite, chemical changes have frequently taken place in the minerals of the rock. After discussing the chemical constitution of the rock, and of its various constituents, and the relation between the micropegmatite and the surrounding minerals, the author pointed out that three methods for the formation of the micropegmatite may be conceived of: (α) during the primary consolidation of the magma; (β) by secondary changes induced in the rock; (γ) by subsequent intrusion of granophyric material into the augite-plagioclase rock. In opposition to (γ), the author pointed out the entire absence of granitic intrusions in the neighbourhood. He regarded the absence of all proofs of subaerial hydration, and the remarkable freshness of the rocks as precluding the possibility of the micropegmatite having been formed by secondary change. The primary origin of the micropegmatite he believed to be proved by (1) the crystallographic continuity of its felspar with that of the normal plagioclase of the rock; (2) the mode of occurrence of the micropegmatite, filling in the angles and spaces between the augite and the plagioclase; and (3) its variation in coarseness of grain agreeing with that of the remaining two constituents of the rock. An interesting discussion took place upon the question of the primary or secondary origin of the micropegmatite in basic rocks.—The laccolites of Cutch and their relations to the other igneous masses of the district, by the Rev. J. F. Blake. The author has observed thirty-two domes of various kinds in Cutch, distributed as follows: (i.) those connected with the northern islands; (ii.) those of Wagir; and (iii.) those along the northern edge of the mainland. They are divisible into four classes: (*a*) those which are so elongated on the line joining adjacent ones that they seem to be mere modifications of anticlinals, though the supposed anticline is not really continuous; (*b*) those which lie in a line, but are not elongated in that direction, and often in no other; (*c*) those which are related to a fault, which cuts them in half; and (*d*) those which are not in any particular relation to each other, or to any other stratigraphical feature. The domes varied in degree of perfection: some were irregular, while some had the strata running in concentric circles, the outer and newer strata dipping away from the inner and older. In no less than ten of the thirty-two domes igneous bosses were found occupying the centre, and these were distributed amongst all of the above classes. The author gave reasons for maintaining that the domes were the results of intrusion of igneous rocks in the

form of laccolites, and were not anticlinal folds which have afterwards been affected by cross-folds. The domes were contrasted with igneous peaks which occurred in abundance in a different part of the area, usually at a higher horizon of the strata and at a higher level above sea. These were probably volcanic pipes through which the lava was forced and extruded at the surface. The author compared the rocks of the bosses with those of the dykes and flows. Both were principally perfectly fresh dolerites, but the former were distinguished by the presence of intergrowths of micropegmatite as the last stage of consolidation, as in the "Konga diabases." There was also among them a felsite-breccia with micropegmatite developed in the cracks. He considered that nearly all the igneous rocks of Cutch had been derived from a single magma, which in a solid condition must have contained large crystals of augite, olivine, and ilmenite in a ground-mass of lime-felspars, and have been throughout of a basic character. Such a magma originated in more than one centre.

Zoological Society, June 1.—Dr. Albert Günther, F.R.S., Vice-President, in the chair.—A communication was read from Dr. John Anderson, F.R.S., containing a water-colour drawing of the Egyptian weasel (*Mustela subpalmata*), taken from living specimens which he had recently presented to the Society's menagerie. Dr. Anderson also sent some remarks on this rare Egyptian mammal, and others were made by Mr. E C. Taylor.—A communication was read from Prof. T. W. Bridge, on the morphology of the skull in the Paraguayan Lepidosiren and other Dipnoi.—A paper on the classification of the *Thyrididæ*, a family of the Lepidoptera Phalænæ, by Sir George F. Hampson, Bart., was read. It contained short diagnoses of the twenty-six known genera (of which *Pycnosoma* and *Plagiosella* were described as new) of the group, and a list of the known species of each genus.—A second communication from Sir George Hampson treated of the classification of the *Chrysauginæ*, a subfamily of moths of the family *Pyralidæ*. Like the preceding paper, it contained diagnoses of the known genera, of which seventy-six were enumerated, and a list of the known species of each genus. Of the genera the following were characterised as new:—*Hyalosticta*, *Protrichia*, *Prionidia*, *Microzancla*, *Sarcistis*, *Monoloxis*, *Dilaxis*, *Tetraschistis*, and *Cyclopalpia*.—Dr. A. G Butler read a paper on a collection of Lepidoptera obtained in East Africa in 1894 by Mr F. Gillett. Fifty-seven species were enumerated, and the dates of the capture of the specimens were recorded.—Dr. C. I. Forsyth Major read a paper on the Malagasy genus of rodents *Brachyuromys*, and entered into the question of the mutual relation of some of the groups of the *Muridæ* (*Hesperomyinæ*, *Microtinæ*, *Murinæ*, and *Spalacidæ*) with each other and with the *Nesomyinæ* of Madagascar. The Malagasy Rodentia were considered as forming a subfamily *Nesomyinæ*, the lowest of *Muridæ*, being forerunners of the American *Hesperomyinæ*, the Old-World *Murinæ* and the *Microtinæ* (*Arvicolinæ*). One of the genera from Madagascar (*Brachyuromys*) was stated to bear close affinities to a genus of the *Spalacidæ*. Reasons were given for regarding the last-named family as only lowly-organised *Muridæ*.

CAMBRIDGE.

Philosophical Society, May 10.—Prof. Liveing, Vice-President, in the chair.—Observations on stomata by a new method, by Mr. Francis Darwin, President. The method consists in the use of "Chinese sensitive leaf," *i.e.* thin sheets of horn treated in a special manner. When a strip of this substance is placed on the stomatal surface of a leaf, it gives evidence of the condition of the stomata by its movement. If they are open, it curves away from the source of moisture; if shut, it remains stationary. By means of a simple apparatus the degree of curvature of the horn is recorded. All the ordinary experiments with stomata can be easily and rapidly shown with a hygroscope of this sort. By taking readings at regular intervals the diurnal course of the stomata can be studied; in this way it has been shown that the nocturnal closure of the stomata is a periodic phenomenon like the "sleep" of leaves. A number of observations were made on the effects of the withering of leaves on the stomata: it was shown that while the stomata of certain species simply close as the leaf withers, in others the first effect is a well-marked opening. This fact is of interest in connection with the mechanism of the stomata, since it indicates the share which the pressure of the surrounding epidermic cells has on the guard cells. It was shown that many plants open their stomata in long-continued darkness; this fact bears on the mode of action of the guard cells, since it shows that they do not (as is often assumed) lose their turgescence when the assimilation of CO_2 is prevented.—Notes on hybrid Cinerarias produced by Mr. Lynch and Miss Pertz, by Mr. Bateson. It is stated by many writers that the garden Cineraria arose as the hybrid offspring of several species of *Senecio* from the Canary Islands. This statement has been questioned by Mr. Thiselton Dyer on various grounds. The author exhibited hybrids raised from *S. cruentus*, *S. multiflorus*, and *S. Heritieri* (= *lanatus*) raised in the Cambridge Botanic Gardens by Mr. Lynch and Miss Pertz, which illustrated the very great variability which appears in the offspring of the various crosses In particular, specimens of *Heritieri* ♀ × *cruentus* ♂ and of the reciprocal cross were produced, showing excessive variability and proving how greatly the peculiar characters of *Heritieri* may be obscured in the offspring, even of the first cross. Five specimens of *multiflorus* ♀ × *Heritieri* ♂ were exhibited, each of which was exceedingly distinct from the rest. Experiments had entirely confirmed Darwin's observation that Cinerarias are self-sterile in a high degree. They hybridise, on the contrary, with great readiness. An accidental hybrid between *Heritieri* ♀ × garden Cineraria ♂ and the reciprocal were also shown, the two plants being quite unlike each other. One seedling *multiflorus* ♀ × garden Cineraria ♂ had been produced which was almost entirely female, a few anthers only appearing in later inflorescences. These experiments were to be continued; but so far as they had gone, they were entirely consistent with the view that the Cineraria was a hybrid between several species, *cruentus*, *Heritieri* and, probably, *multiflorus* being among them. The two first are named by most writers as probable parents.

PARIS.

Academy of Sciences, June 8.—M. A. Chatin in the chair.—On the periods of double integrals, and the development of the disturbance function, by M. H. Poincaré.—General theory of gradually varied conditions in the friction of liquids with vortices; formulæ of the first approximation, by M. J. Boussinesq.—Action of light upon mixtures of chlorine and hydrogen, by MM. Armand Gautier and H. Hélier. The influence of moisture upon the combination of the two gases under the action of light was first studied. When water is present the velocity with which hydrochloric acid is formed is considerably increased, this effect being probably produced by the lowering of the partial pressure of the hydrogen chloride formed. The effect produced by exposure for different periods to standard artificial light was also studied. If either gas is in excess, the reaction is much accelerated.—Observations on the limitation of chemical reactions, with especial regard to the preceding communication, by M. Berthelot.—Reply of M. Armand Gautier to M. Berthelot.—Note by M. Berthelot accompanying the presentation of his work on "Thermochimie."—A new truffle (*Terfezi aphroditis*) from the Isle of Cyprus, by M. Ad. Chatin. This truffle is characterised by its dark colour, being known locally as the black truffle. It frequently attains a very large size, one weighing 385 grams having been found in 1873.—Micrometric measures of double stars made at St. Petersburg and Domkino by Prof. S. de Glasenapp, Director of the Imperial University of St. Petersburg, by M. Loewy.—Examination of some spectra, by M. Lecoq de Boisbaudran. A reply to some criticisms of Eda and Valenta.—A Committee was appointed to present a list of candidates for the Foreign Associateship, rendered vacant by the death of M. Tchébychef.—Theoretical and practical study of the lung, its functions and diseases. Tuberculosis and its clinical cure, by M. H. Grasset.—On surfaces having the same spherical representation, by M. A. Pellet.—Remarks on a recent note of J. M. Weber, by M. E. Goursat.—On real systems of complex numbers, by M. E. Cartan.—Properties of the simple kathodic rays. Relations with simple electric oscillations, by M. H. Deslandres. An electrified body, interposed in the path of a kathode ray, causes an enlargement of the shadow, the kathode bundle being divided up into several distinct and unequally deviated bundles. These bundles are called simple kathodic rays, and it is shown that they correspond to simple electric oscillations.—On the atomic weight of cerium, by MM. Wyrouboff and A. Verneuil. Having shown in a preceding paper that it is possible to prepare cerium oxide in a state of high purity, this specimen has been utilised to fix the atomic weight of the metal. The sulphate was carefully purified from free sulphuric acid by repeated precipitation with alcohol or by careful ignition, and the atomic weight determined by

three methods, namely, from the loss of water of the hydrated sulphate at 250° (92·70), from the ratio C_3O_4: hydrated salt (92·83), and from the ratio C_3O_4: dry salt (92·87), the mean result being about 92·7.—On the heat disengaged by the addition of bromine to some unsaturated substances, by MM. W. Louguinine and Iv. Kablukov. The unsaturated substances, for which results are given, include allyl chloride, ethyl allyl ether, allyl acetate, crotonic aldehyde, mesityl oxide and cinnamic alcohol.—Combinations of phenylhydrazine with metallic bromides, by M. J. Moitessier. Compounds of phenylhydrazine with the bromides of zinc, cadmium and magnesium are described.—On a menthoglycol, by MM. Ph. Barbier and G. Leser.—Chemical study on the culture of *Cattleya*, by MM. Alex. Hébert and G. Truffaut.—The use of aluminium vessels, by M. Balland. A method of treatment is described which permits of the rapid examination of aluminium water-flasks and other vessels used for military purposes.—The bacteria of boghead cannel, by M. B. Renault. The presence in boghead coal of an extremely small micrococcus is proved, to the chief of which the name *Micrococcus petrolei* is given.—Study of the infectious lesions of the bubonic plague, by M. Gustave Nepveu.—Researches on the Ostioles, by M. J. J. Andeer.—On the mechanical impossibility of the geometry of Lobatschewsky, by M. Jules Andrade.

DIARY OF SOCIETIES.

THURSDAY, JUNE 17.

ROYAL SOCIETY, at 4.30.—An Experimental Research upon Cerebro-Cortical Afferent and Efferent Tracts: Prof. Ferrier, F.R.S., and Dr. Turner.—On the Relative Behaviour of the H and K Lines of the Spectrum of Calcium: Dr. and Mrs. Huggins.—(1) Further Observations of Enhanced Lines. (2) The Total Solar Eclipse of August 9, 1896. Report on the Expedition to Kiö Island. (3) On the Classification of the Stars of the δ Cephei Class: J. Norman Lockyer, F.R.S.—On the Action exerted by certain Metals and other Substances on a Photographic Plate: Dr. W. J. Russell, F.R.S.—Stress and other Effects produced in Resin and in a Viscid Compound of Resin and Oil by Electrification: J. W. Swan, F.R.S.—On Lunar and Solar Periodicities of Earthquakes: Prof. A. Schuster, F.R.S.—Kathode Rays and some Analogous Rays: Prof. S. P. Thompson, F.R.S.—And other Papers.

LINNEAN SOCIETY, at 8.—On the Distribution of *Primula elatior*, Jacq.: Miller Christy.—On the Acari collected by Mr. H. Fisher, Naturalist of the Jackson-Harmsworth Polar Expedition, at Cape Flora, Northbrook Island, Franz-Josef Archipelago, in 1896: A. D. Michael.—Further Observations on Stipules: Sir John Lubbock, Bart., F.R.S.—On Minor Tension Lines between Plant Formations: Prof. Conway Macmillan.

CHEMICAL SOCIETY, at 8.—Ballot for the Election of Fellows.—The Reduction of Perthiocyanic Acid: F. D. Chattaway and H. P. Stevens.—Molecular Refraction of Dissolved Salts and Acids, Part II.: Dr. J. H. Gladstone, F.R.S., and W. Hibbert.—On a Space Formula for Benzene: Prof. J. Norman Collie, F.R.S.—On the Production of some Nitro- and Amido-oxypicolines: Dr. A. Lapworth and Prof. J. Norman Collie, F.R.S.—The so-called Hydrates of Iso-propyl Alcohol; Dr. T. E. Thorpe, F.R.S.—The Carbohydrates of the Cereal Straws: C. F. Cross, E. J. Bevan, and C. Smith.—Further Experiments on the Absorption of Moisture by Deliquescent Substances: H. Wilson Hake.

MINERALOGICAL SOCIETY, at 8.—On Blödite from the Punjab: F. R. Mallet.—On Monazite and Xenolime in European Rocks: Orville A. Derby.—On the Identity of Sundtite and Webnerite: G. T. Prior and L. J. Spencer.

FRIDAY, JUNE 18.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Sub-Oceanic Changes: Prof. John Milne, F.R.S.

SATURDAY, JUNE 19.

GEOLOGISTS' ASSOCIATION—Excursion to Leighton Buzzard. Director: A. C. G. Cameron. Leave Euston, 9.10 a.m.; arrive Leighton, 10.47 a.m.

MONDAY, JUNE 21.

VICTORIA INSTITUTE, at 4.30.

TUESDAY, JUNE 22.

ROYAL STATISTICAL SOCIETY, at 5.—Annual General Meeting.

WEDNESDAY, JUNE 23.

GEOLOGICAL SOCIETY, at 8.

FRIDAY, JUNE 25.

PHYSICAL SOCIETY, at 5.—A New Theory of the Earth's Magnetism; Mr. Sutherland.—Experiments in Critical Phenomena; Dr. Kuenen.—On the Attenuation of Electric Waves in Wires: Dr. Barton.—On the Steady Motion of an Electrified Ellipsoid: G. F. C. Searle.

SATURDAY, JUNE 26.

GEOLOGISTS' ASSOCIATION.—Excursion to Red Hill and Merstham (New Railway). Directors: Dr. G. J. Hinde, F.R.S., and W. Whitaker, F.R.S. Leave Cannon Street Station (S.E.R.) at 1.35 p.m.; arrive at Red Hill, 2.21 p.m.

LONDON GEOLOGICAL FIELD CLASS.—Excursion—Aylesford to Maidstone. Lower Greensand. Leave Cannon Street, 2.37; arrive Aylesford, 4.9.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—In Garden, Orchard and Spinney, Phil Robinson (Isbister).—The Dolmens of Ireland: W. C. Borlase, 3 Vols. (Chapman).—The Woodland Life: E. Thomas (Blackwood).—The Collected Mathematical Papers of Arthur Cayley, Vol. xii. (Cambridge University Press).—Électro-Métallurgie: A. Minet (Paris, Gauthier-Villars).—Grundprobleme der Naturwissenschaft: Dr. A. Wagner (Berlin, Gebrüder Borntraeger).—Introduction to Philosophy: Prof. O. Külpe, translated by W. B. Pillsbury and E. B. Titchener (Sonnenschein).—The Fertility of the Land: Prof. I. P. Roberts (Macmillan).—Human Embryology: Prof. C. S. Minot (Macmillan).—The Psychology of the Emotions: Prof. Th. Ribot (Scott).—Grundriss der Entwickelungsmechanik: W. Haacke (Leipzig, Georgi).—Nouvelle Étude sur les Tempêtes, &c.: H. Faye (Paris, Gauthier-Villars).—Life in Early Britain: Prof. B. C. A. Windle (Nutt).

PAMPHLETS.—L'Ora Esatta Dappertutto: Dr. M. Rajna (Milano, Hoepli).—On the Origin of the European Fauna: Dr. R. F. Scharff (Dublin, Ponsonby).—Epistolæ quas per Annos a 1596 ad 1601: Tycho Brahe et Oligerus Rosenkrantzius (Havniae).

SERIALS.—Proceedings of the Physical Society of London, June (Taylor).—Geographical Journal, June (Stanford).—Journal of the Asiatic Society of Bengal, Vol. lxv. Part 2, Nos. 3 and 4; and Part 3, No. 1 (Calcutta).—American Journal of Science, June (New Haven).—Abhandlungen zur Physiologie der Gesichtsempfindungen aus dem Physiologischen Institut zu Freiburg i. B., Erstes Heft (Hamburg, Voss).—Aeronautical Journal, 1897. No. 3 (Boston, Clarke).—Atti della Fondazione Scientifica Cagnola della sua Istituzione in Poi, Vol. xiv. (Milano).—Memoire del R. Istituto Lombardo di Scienze e Lettere, Vol. xx., xi. sella, serie iii. Fasc. 1–4 (Milano, Hoepli).—Journal of the Chemical Society, June (Gurney).—Bulletin of the American Mathematical Society, May (New York, Macmillan).—Himmel und Erde, June (Berlin, Paetel).—Journal of the Franklin Institute, June (Philadelphia).—American Naturalist, June (Philadelphia).—Transactions of the American Microscopical Society, Vol. xviii. (Buffalo, Brown).—McClure's Magazine, June (New York, McClure).

CONTENTS.

THURSDAY, JUNE 24, 1897.

1837—1897.

THERE has been one feeling in the minds of the inhabitants of Britain, and of Greater Britain, during the last week, which has thrown all others into the shade—a feeling of intense patriotism and loyalty to the Queen, mixed with a deep reverence for her personal qualities. It is this feeling which has brought representatives to our shores from every part of the greatest empire which so far the world has known; which has organised the stupendous ceremonial witnessed on Tuesday in the metropolis, a celebration to be worthily crowned on Saturday by the review of the first line of the armed force of the nation.

These most memorable events in the annals of our time—events, indeed, beyond all precedents of former times—which have so emphatically marked Her Majesty's Diamond Jubilee, have naturally been connected in many minds with the progress of the nation during the last sixty years. It is satisfactory to note the general recognition in the daily and weekly press of the importance of the part played by science during that interval in securing the tremendous advance which has been achieved, along many lines, in things pertaining to the increased well-being and usefulness of mankind.

It is very generally recognised that the Victorian age is emphatically the age of science, and indeed so true is this that a hasty sketch of the progress of natural knowledge during the last sixty years would require a volume. So great has been the advance, so rapidly are all benefits conferred by science applied to our daily needs, that it is extremely difficult already to obtain a mental image of many conditionings of life sixty years ago, and it is not a little singular that many of the advances made, which in some cases have profoundly influenced modern thought, and in others have enormously increased the happiness, comfort and usefulness of our lives, are very nearly conterminous with the reign.

How changed are the Imperial conditions even from the year of the famous Great Exhibition, when, in the language of Tennyson, there were poured upon our shores,

> ——"Things of beauty, things of use
> Which one fair planet can produce,
> *Brought from under every star.*"

In the year 1837 the possibility of telegraphy was first realised, and Faraday was at work at frictional electricity. Who can attempt to measure the value of this early electrical and magnetic work, either from the pure science or applied science point of view? Has not the close binding together of the various units of the Anglo-Saxon race which has brought citizens of the Empire from under every star been among the indirect results?

From that year to the present time not a sea, but an ocean of marvels has been discovered. Our view has been obscured by day with wires carrying currents, some of which illuminate our cities and houses at night, while others carry our messages to the ends of the earth. Surely in all this progress in one restricted branch since 1837 we have a clear indication that the study of the useless—useless because it has never been used—is the surest way to discoveries rich in public utility.

It has also been recently pointed out that the art and science of photography are conterminous with the reign.

> "In 1837 Daguerre and Fox Talbot were founding photography. The Daguerrotype and Talbotype were given to the world two years later. What would the modern world do without photography, as we know it in this year of Jubilee? It has added ten thousand million stars to the astronomer's stock-in-trade; it is an invaluable ally in the study of the physics and chemistry of distant worlds; while with a grand impartiality it reveals to us the secrets of the infinitely little. Last of all, not content with adding to the pleasures and the knowledge of mankind, it comes to succour human ills, and soon no hospital will be without its aid."

We may note with pride that in the Victorian era Britain has well retained her place, not to say her supremacy, in the realm of ideas. One of the great poets—the makers—of science whose name will go down to posterity with that of Newton has added lustre to the Queen's reign.

But we may warmly congratulate ourselves that something more than science itself has advanced; the importance of its methods and results in relation to the future progress of the nation is at last receiving a tardy recognition.

The progress of science itself and its results are naturally not confined to any one nation under the new world condition of almost instantaneous exchange of thought, but this same possibility of rapid exchange also applies to the transit of raw material. Britain in the past had for years a practical monopoly of coal and iron; this was her strength, but this strength is hers exclusively no longer.

At the present day Britain is distinctly behind Germany in the national endeavour to face the conditions of national peaceful competition as they exist. Our Government has been supine in matters in which the German Government have put forth all their strength, and so, even assuming that the scientific spirit and the individual endowment and advancement have been the same in both countries, we have fallen sadly into arrear as to those educational and scientific institutions on which we must depend for the future production of workers and new discoveries.

There are signs that this condition of things is mending, that the error is being acknowledged by those who, if they choose, can readily correct it. The Duke of Devonshire last week, at the opening of the International Congress on technical education, announced frankly: "We have in this country a Department of Education, but its functions are almost entirely limited to elementary education, and we have not in our Administration any minister who properly corresponds to the Minister of Education of other Governments."

It is as if one should say, "We have in this country a Department of War, but its functions are almost entirely limited to teaching the goose-step to recruits."

Another encouraging sign is to be found in the recent increase in the assistance rendered to the University Colleges, all of which outside the metropolis have been

founded during Her Majesty's reign. At the same time the establishment of similar institutions in other localities is encouraged by the promise of grants to them also under certain specified conditions. But in relation to our advance in this direction, it is a matter of regret to all friends of the higher education that the so-called University of London, which was established in the year before Her Majesty came to the throne, is not yet a University in the true sense. Is it too late to hope that the Jubilee year may yet be signalised by bringing London in this matter up to the level of the smaller cities of the world?

In still another direction an important advance must be noted. We refer to the inclusion of men of science among those upon whom the Sovereign confers distinction for services rendered to the State. More than forty years ago the Queen expressed her desire to include among her Privy Councillors two distinguished men of science, and yet, owing to one cause and another, the conferring of this distinction upon a man of science did not take place till a few years ago, when Huxley was enrolled among the members of that body. There are signs that the opinion is rapidly growing that if the function of a Privy Council is to give wise counsel in the nation's need, the increased utilisation of science in every part of the national machinery, whether it deal with the arts of peace or war, renders it not only desirable but necessary that the ranks of the Privy Council shall be strengthened in this direction. There can be little doubt that in a not distant future the Lords of the Committee of the Privy Council who deal with matters concerning science will contain among them many members of the Royal Society.

There is also another matter to be considered in relation to the Queen's reign. It is the steady increase in the usefulness, the utilisation, and the dignity of the Royal Society. This throws an ever-increasing responsibility upon its Officers, Council and Fellows, among other things in the selection of their successors.

Other vast fields of activity are gradually and necessarily being added to the original ones of discussion and publication, and wisdom as well as knowledge is now essential in the proper direction of its energies. The view, therefore, still held by some, that the Society is a kind of superior college of preceptors of a strictly limited number of branches of knowledge, is rapidly disappearing as Her Majesty's reign continues.

At the present time, on the one hand, the Government does not hesitate to consult the Society when need arises, and, on the other, it rarely refuses to accede to demands made upon it to assist research in various directions where the State influence or machinery, or both, can be utilised. The memorable voyage of the *Challenger* and various eclipse expeditions are excellent cases in point. The gigantic work recently undertaken by the Society in organising the production of an International Catalogue of Scientific Literature has only been rendered possible by the sympathy and assistance of the Government; and the more similar works of large grasp the Society is connected with in the future, the more respected British science will be all the world over, for the responsibility of the Royal Society is no longer confined to these islands.

DUCAL HUSBANDMEN.

A Great Agricultural Estate, being the Story of the Origin and Administration of Woburn and Thorney. By the Duke of Bedford. Pp. 254. (London: John Murray, 1897.)

First Report on the Working and Results of the Woburn Experimental Fruit Farm. By the Duke of Bedford and Spencer Pickering, F.R.S. Pp. iv + 194. (London: Eyre and Spottiswoode, 1897.)

ONE is tempted to believe that agriculture has been in the blood of the Russell family not only by inheritance, but by heredity. It has been to the Earls and Dukes of Bedford what politics has been to some families and drink to others—a deadly recurrent outbreak. It apparently began with a lady, the wife of the third Earl, who, according to Sir William Temple, contrived "the perfectest figure of a garden" at Moor Park. Her offspring in successive generations have been famous improvers of estates, plantations, fields and gardens. It was John, the fourth Duke, who in defiance of the remonstrance of the celebrated Philip Miller, his gardener, thinned his famous plantation of pines and firs, and so that there might result no injury to Miller's reputation as a planter, caused a board to be fixed in the plantation, facing the road, on which was inscribed, "This plantation has been thinned by John, Duke of Bedford, contrary to the advice and opinion of his gardener." The draining, planting and experimenting has gone forward almost continuously from the time when Francis, the fourth Earl, devoted attention, capital and reputation to draining the fen lands. The great drainage works of the Romans, maintained by the monks of Thorney, Crowland, Ely, &c., had fallen out of repair by the end of the sixteenth century, and "it was only on the maps that the rivers [of the fen country] ran into the sea" when he undertook the task afresh. The reward for this, as related by the present Duke, was that Charles I. sent Earl Francis to the Tower, and his son Earl William, who incurred the enmity of the Parliament during the Civil War, had his estates sequestrated for a time. But through bad times and good the Bedfords have been of like mind with Sir Walter's Laird of Dumbiedikes, who, on his death-bed, remarked, "Jock, when ye hae naething else to do, ye may be aye sticking in a tree; it will be growing, Jock, when ye're sleeping." The present Duke has, fortunately both for science and practice, not only maintained the famous Woburn experiments, but has broken out in a new place with the establishment of a splendid experimental fruit farm, designed quite as much for purely scientific as for economic ends. With the scientific advice of Mr. Pickering, who in this matter also appears to his fellow scientific workers in a new character, this great garden has been laid out and the work of record begun. Even in these first years results of interest appear, but they are small compared with what future generations will reap. It is difficult from this first Report to gather more than admiration of the plan; but those who have seen the fruit farm, cannot fail to have carried away the conviction that it is one of the most notable experiments in rural economy now in progress.

In addition to this solid service, his Grace has compiled a statistical account of the management of the estates of

Woburn and Thorney as material for a discussion of the land question. To review it adequately here is impossible, since it would lead one straightway into political discussion. The returns from the Beds, Bucks and Thorney estates, as set forth in the appendix, show the following financial results. "On Thorney the expenditure, from 1816 to 1895, amounted to 1,598,353*l*., and on Woburn, from 1816 to 1895, it was 2,632,186*l*. After spending nearly four and a quarter millons sterling since 1816 on some 51,643 acres of land, a large proportion of which is some of the best wheat land in England, and after excluding all expenditure on Woburn Abbey, its park and farm, it will be seen that at the present time an annual loss of more than 7000*l*. a year is entailed on their owner." Elsewhere we read: "As to the pleasures to be derived from the ownership of an estate like Thorney, if the reader conjures up a beautiful mansion and park with endless game preserves he is mistaken. They do not exist. The only pleasure which I and my forebears can have derived from Thorney is the kindly feeling which has existed," &c. It would be a fatal mistake to suppose that the Duke has compiled these tables of statistics, and written this most interesting book to demonstrate the philanthropic principles of his ancestors, or to justify his own position as a landlord—"such pride is hardly wrong," as Mr. Gilbert sings—but rather to enable him to have a fling at John Stuart Mill, and to justify all landlords. Without entering on politics, one may point to the weak spot in his argument. He innocently fancies all or most landlords to be as the Russells. If they were, the land agitator would carry on his operations with a plough.

GEORGE MURRAY.

AN ISLAND OF THE EASTERN ARCHIPELAGO.

With the Dutch in the East. By Captain W. Cool (Dutch Engineers). Translated by E. J. Taylor. Pp. viii + 365. (London: Luzac and Co., 1897.)

THE past few years have been marked in a peculiar degree by disturbances in the various colonial dependencies of European nations. Not only in Central Africa—where the recent forward movement for the opening up of the continent has naturally led to collisions with native races—but in many of the older colonies in other parts of the world, it has been necessary for the paramount power to maintain its supremacy by force of arms. The recently translated work of Captain W. Cool gives a detailed narrative of one such war, undertaken by the Dutch in 1894 to deliver the subject population of the island of Lombok from the oppression of their Balinese rulers. The author tells the story of the expedition in a somewhat dramatic style, giving it almost the complexion of a national epic. In fact, accustomed as we are in this country to such small colonial wars, we might be inclined to think that he has attempted to raise it to a level unwarranted by the facts of the case. But the expedition had an importance beyond what might appear at first sight. It may even be said to have formed in some way a turning-point in Dutch colonial history. The difficulties encountered during the Achin war, and the unfortunate experiences of the Flores expedition had seriously threatened the Dutch prestige in the archipelago, and failure or only partial success at Lombok might have been regarded as indicating that Holland was now unequal to the task of maintaining her hold on her extensive colonies in the East. In spite of some reverses, which necessitated the dispatch of considerable reinforcements, the general result of the war was fortunately most successful, and will, it may be hoped, have conferred a lasting benefit on the island in the form of good and settled government for the future.

English literature on the subject of the Eastern Archipelago is so scanty, and the works of Dutch writers—naturally by far the most numerous—are so little known in this country, that any addition to our knowledge of that part of the world is welcome. With regard to Lombok, we believe that almost the only information—obtained at first hand—to be found in English works, is that contributed by Dr. A. R. Wallace, who, in 1856, crossed from side to side of the island; and in his "Malay Archipelago" devotes two interesting chapters to the manners and customs of the people. Apart from the story of the military operations, Captain Cool gives, in his third and fourth chapters, a useful summary of all that is known of the island and its inhabitants, with a sketch (considerably shortened in the English translation) of the connection of the Dutch with it from the time of their first voyages to the Far East. Being confined to the neighbourhood of the west coast, the expedition did not, unfortunately, add much to our knowledge of Lombok, which, though small compared with other islands of the archipelago, is still little known apart from a narrow strip across the centre. Captain Cool's information is therefore necessarily compiled in great part from previously published works, those of Zollinger and Jacobs in particular being largely drawn upon. He gives a most unpleasant picture of the state of morals in the island, the Brahminical Balinese rulers being decidedly worse in this respect than the subject Mohammedan Sassaks. The oppression and tyranny of the former is likewise painted in strong colours, although Wallace thought the Sassaks in his time reconciled to their then new rulers. The island has undoubtedly everything to gain from being brought more closely under the influence of the Dutch authorities.

The author's style is one which hardly lends itself well to exact reproduction in English, and might perhaps with advantage have been somewhat modified by the translator. The short paragraphs, constant use of question and answer, and of the note of admiration, are apt to be worrying. The book contains a sketch-map of Lombok, and some good illustrations, both of scenery and people, and is provided with a full and well-arranged index.

OUR BOOK SHELF.

Die elektrodynamischen Grundgesetze und das eigentliche Elementargesetz. Von Franz Kerntler. 8vo. Pp. 68. (Budapest: Buchdruckerei der Pester Lloyd-Gesellschaft, 1897.)

THOSE who take up the present book with the expectation of finding in it a full and comprehensive sketch of the principles of electro-magnetism will be disappointed. Dr. Kerntler's work might, perhaps, be best described as an essay on "Ampère's Law and Allied Theories,"

since it deals exclusively with that debated point, the action of two elements of current on one another.

So long as Maxwell's theories of the mutual induction of closed circuits are taken as the starting-point, a certain indeterminativeness must inevitably arise in the endeavour to isolate the effects of separate portions of the circuits. It is with the various rival hypotheses required to complete the solution of the problem that the present investigation deals. In the first section we have an account of Ampère's hypothesis and the laws of force resulting from it. The next section deals with the most general law of force, based on the law of the inverse square; this is followed by a section devoted to Maxwell's investigations, and finally Dr. Kerntler propounds a new law of force which, he claims, is free from the objections raised by him against Ampère's, Neumann's, Weber's, and other formulæ. This law is merely obtained by assigning certain values to the arbitrary constants which occur in the expressions for the force-components, and which satisfy the relations found by Stefan. The subsequent applications of the proposed law to finite portions of conductors form an interesting collection of problems.

An important feature is that the author divides the various hypothetical laws into two categories—those which are applicable to determine the action between closed circuits only, and those which give correct results when used to find the action of a closed circuit on an element of current.

In former times, when the doctrine of action at a distance held the field, such an investigation as the present would, doubtless, have attracted many supporters, between whom and the advocates of Ampère's and other laws a spirited controversy might have arisen. At present we have become so accustomed to regarding the seat of electro-magnetic action as residing in the dielectric, that it is difficult to regard any investigation of direction action and reaction between two elements of current as being of more than purely academical interest. Still, the fact that many of our text-books base their introductory treatment, both of electrostatics and of magnetism, on the theory of action at a distance renders it desirable that interest should be resuscitated in these attempted solutions of the corresponding problem for electric currents; and for this, if for no other reason, the present endeavour to establish a new formula cannot fail to be worthy of the attention of physicists. G. H. B.

Catalogue of Tertiary Mollusca. Part i. The Australasian Tertiary Mollusca. By George F. Harris. Pp. xxvi + 407. Eight plates. (London: Printed by order of the Trustees of the British Museum, 1897.)

Catalogue of the Fossil Cephalopoda. Part iii. The Bactritidæ and part of the sub-order Ammonoidea. By Dr. Arthur H. Foord and George Charles Crick. Pp. xxxiii + 303. Illustrated. (London: Printed by order of the Trustees of the British Museum, 1897.)

THE present work by Mr. Harris commences a new catalogue. This first part is devoted to descriptions and figures of the shells of Australasia (exclusive of Cephalopoda), and will be followed, in due course, by other geographical series in the collection. The larger part of the Mollusca and Bryozoa, and the whole of the Brachiopoda, Annelida, Arthropoda, Echinoderma, and Cœlentera, still remain to be recorded, as well as the greater portion of the fossil plants. When complete the catalogue will include at least thirty volumes, and will then contain no more than a brief account of these extensive collections in the Natural History branch of the British Museum.

The classes of Australasian Tertiary Mollusca described by Mr. Harris in the volume under consideration include the Gasteropoda, the Scaphopoda, and the Lamellibranchiata, and the author rightly points out that their study cannot fail to shed much light on certain questions relating to phylogeny, and to assist the zoologist in tracing the origin of many of the principal groups of these divisions of the Mollusca.

The eight plates, drawn by Miss G. M. Woodward, which accompany the text, are of the usual high order of excellence one associates with the publications of the Trustees of the British Museum.

The volume dealing with the Cephalopoda is mainly the work of Mr. Crick, though Dr. Foord, notwithstanding his removal to Dublin, has rendered all the assistance possible, in order to carry the work through the press. As Dr. Woodward points out in his preface, this addition to the catalogue will prove of extreme importance to all those who desire to study the phylogeny of this group, for we are here presented with conclusive evidence that the Goniatites almost imperceptibly pass into the Ammonites. The figures, of which there are one hundred and forty-five, prepared, with few exceptions, by Miss Woodward, assist very much in making the text clear.

The Story of the Mine, as illustrated by the Great Comstock Lode of Nevada. By Charles Howard Shinn. Pp. x + 272. (London: Gay and Bird, 1897.)

WE learn from the editor's preface that this volume is one of a series intended to explain how the Western States of America were explored, how cities sprang up in desert wastes or among mountains difficult of access, and how gradually these States have become the home of a thriving population. The part played by the miner in the wonderfully rapid development of the Great West is dealt with by Mr. Shinn in a masterly manner.

Taking the Comstock Lode as a typical example, he draws a vivid picture of the early prospecting and subsequent working. The pathetic story of the first discoverers, the brothers Grosh, who both perished before they could reap the fruits of their skill and energy, is probably unknown to most English readers; soon they were followed by hardy but ignorant prospectors, who began by working the gold which they chanced to find in the earth thrown up by a gopher, and threw away as valueless the very rich silver ore which accompanied it. An assay of the "blue stuff," carried by a farmer to a distant town, revealed the true wealth of the marvellous vein; but difficulties of all kinds beset the miner in his endeavours to work it. How they were overcome by pluck, perseverance and science, is told in Mr. Shinn's pages; these should be read by every student of mining, for he may glean from them much valuable information, which is usually placed before him in a less tempting fashion in his dry technical manuals. Numerous illustrations add value to the text. The view of the Belcher Mine shows very clearly how the huge underground excavations are supported by "square sets," and might well be copied as a diagram for teaching purposes. The picture of hydraulic mining is excellent, and decidedly better than some similar illustrations which appear in text-books on mining. It is a pity there is no index.

First Stage Sound, Light and Heat. By John Don, M.A., B.Sc. Pp. 307. (London: W. B. Clive, University Correspondence College Press.)

THE syllabus of the Science and Art Department's elementary examination in Sound, Light, and Heat, is the framework upon which this book has been constructed. The facts and phenomena belonging to the branches of physical science named in the title of the book are clearly described, and with due attention to experiment. Teachers of Departmental classes will be attracted to the book by its conciseness, by the summary at the end of each chapter, and by the large number of exercises and problems to be found in its pages.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Great Submergence.

THE glaciation of the hills and glens all over the west of Argyllshire present phenomena which have for many years convinced me that the chief glaciating agent cannot possibly have been what is called an "ice-sheet." Ordinary glaciers, descending from the hills, have probably been concerned more or less. But the main agency has been, in my opinion, heavy "floe," or floating ice, driven by tides and currents during a submergence and a re-emergence of the land to the extent of at least 1500 feet. The main objection to this view has always been the absence of marine deposits, and especially of marine organisms. It is true that we have very few remaining beds of gravel or sand, and in those, as yet, no mollusca have been discovered. But I have never thought this objection a very strong one, because the submergence may not have been under conditions favourable to molluscan life, and dead shells, carried where they never lived, may easily have long ago been dissolved out. Quite recently, however, shells in great variety have been found at high elevations in Ayrshire, by Mr. Smith, of Kilmarnock. Moreover, these are embedded in the true boulder clay. And where these are wanting, marine microzoa have been detected in abundance by the most skilled and distinguished microscopist of the day. Stimulated by these discoveries, I have lately made a closer search for any remains of loose sands or gravels among our hills. That search has been rewarded by finding a well-marked fragment of an elevated sea-beach at the height of 350 feet above the sea, and in this deposit foraminifera have been found in fair abundance. Another place, quite 500 feet above the sea, has yielded similar evidence; and I have now very little doubt that such evidence will accumulate as the result of further search. This, however, is enough to prove a very recent submergence to a depth which would profoundly alter the distribution of sea and land along all our shores, and would divide the county of Argyll into a group of islands. No reasonable limit can be placed to the possible depth of this submergence. I have no theory as to the causes of it. But it may quite as well have been 1500 as 500 feet; and we must yield to any clear evidence of effects which cannot otherwise be explained. I need not say that the evidence, which in the latest years of his life carried conviction to the mind of the late Sir Joseph Prestwich, that there has been very lately in geological history a great submergence, which was comparatively sudden and comparatively transient, is evidence which no geologist can put aside without the fullest and most candid investigation.

ARGYLL.

The Visibility of a Sound Shadow.

TWO months ago I received the following letter from Mr. E. J. Ryves.

"On Tuesday, April 6, I had occasion, while carrying out some experiments with explosives, to detonate 100 lbs. of a nitro-compound. The explosive was placed on the ground in the centre of a slight depression, and, in order to view the effect, I stationed myself at a distance of about 300 yards on the side of a neighbouring hill. The detonation was complete, and a hole was made in the ground 5 feet deep and 7 feet in diameter. A most interesting observation was made during the experiment.

"The sun was shining brightly, and at the moment of detonation the shadow of the sound wave was most distinctly seen leaving the area of disturbance. I heard the explosion as the shadow passed me, and I could follow it distinctly in its course down the valley for at least half a mile: it was so plainly visible, that I believe it would have photographed well with a suitable shutter."

On receiving this note, I asked and obtained permission from Mr. Maxim to be present if a further experiment of the kind were contemplated. I designed and had prepared a special shutter which, on the breakage of an electrical circuit, would in the 40th second make an exposure of about 1/300 second. Unfortunately the battery that I brought with me proved insufficient, so that I had to discard this, and use an ordinary Thornton-Pickard shutter actuated by hand. Neither the exact moment nor duration of the exposure were under such perfect control, and, as events proved, I could not get the exposure until the shadow had passed me. I had, however, fortunately asked Mr. Paul if he would be so good as to take a picture of the explosion with his animatograph. Mr. Hunt, his manager, came himself, and secured a good series.

Returning now to the eye observation: Mr. Ryves informed me he saw the expanding shadow on an intermediate occasion when only about 10 lbs. were detonated. On the day on which I was present (May 19), about 120 lbs. of nitro-compound were detonated, and 10 lbs. of black powder was added to make sufficient smoke to show on the plate. As the growth of the smoke cloud is far less rapid than the expansion of the sound shadow, no confusion could result from this.

At the time of the explosion my whole attention was concentrated upon the camera, and for the moment I had forgotten to look for the "Ryves ring," as I think it might be called; but it was so conspicuous that it forced itself upon my attention. I felt rather than heard the explosion at the moment that it passed. We stationed ourselves as near as prudence would allow at a distance of 120 yards, so that only about one-third of a second elapsed between the detonation and the passage of the shadow; but the precision of observation of coincidence when very rapid movement occurs is so great, that I am quite satisfied that the observation was correct. The actual appearance of the ring was that of a strong black circular line, opening out with terrific speed from the point of explosion as a centre. It is impossible to judge of the thickness of the black shadow; it may have been 3 feet, or it may have been more at first, and have gradually become less in thickness or, possibly, in depth of shade.

I have some difficulty in understanding why the whole ring should be visible if the phenomenon is the same as that which Prof. Mach and I have photographed. In our cases a bullet travelling at a speed greater than that of sound, forms a hyperboloidal shell of compressed air round about it. Light waves passing nearly tangentially, but just entering the shell, are refracted inwards, and thus leave a black line when they fail to strike the photographic plate. As they strike the plate within this black line on a part to which other rays have come nearly direct, an extra bright line is formed within the dark one. That which is essential, however, for the formation of the dark line is the tangency of the incident light.

Now, in the case of a hemispherical explosive wave it is clear that the sunlight can only be tangential over a semicircle, and that the shadow of such a wave should be a semi-ellipse, the eccentricity of which would depend upon the altitude of the sun. There could be no true tangential shadow on the sunward side of the explosion. Observation, however, showed a complete ring. If, as has been suggested to me as possible, the explosive wave does not travel at equal speeds in all directions, but is retarded near the ground, the wave front near the ground might be sufficiently inclined for the sun's rays to be tangential over much more than a semicircle. On May 19, when I made the observation, the sun had an altitude of about 58°, but on April 6, when Mr. Ryves made his first observation, the altitude was only 45°.

Mr. Maxim, with his usual ingenuity, suggested that perhaps what was observed was not a sound shadow at all, but merely a progressive wave bending down of every blade of grass as the explosive wave passed by. This would no doubt occur, and might be visible, but it is difficult to see how so black a ring should be produced in this way.

The animatograph fails to show any black ring; and this is not surprising, as with the exposure of about 1/100 second the shadow would have to be at least 11 feet thick, in order that some part should remain obscured during the whole exposure. If the black line is just without an equal bright line, as in the bullet photographs, and both are taken in by an exposure, it is hardly to be expected that any definite result should be obtained. As a fact, there is clearly seen a circular light shading, which does—so far as one can judge from the supposed rate of working, and the known distances—expand at about the same rate as the observed shadow, but it is lighter than the ground and shaded, instead of being dark and sharp, as seen by the eye.

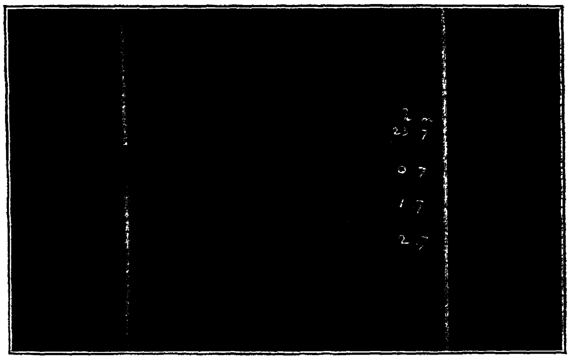
I feel that the imperfect account which I am able to give is of sufficient interest to appear in the columns of NATURE, but I hope that it may induce those who have occasion to detonate heavy charges to make any observations that opportunity allows.

For instance, if the Ryves ring is only visible in direct and brilliant sunshine, that will be evidence in favour of the shadow theory. If it is equally visible when the sun is not actually shining, but when the sky is illuminated by numerous white clouds, that will be evidence of the grass theory.

I may add that our observations were made from the west, and at noon. C. V. BOYS.

An Edinburgh Record of the Indian Earthquake.

A VERY interesting record of the recent earthquake at Calcutta is shown by the photographic apparatus of the bifilar pendulum of this observatory. A few very slight preliminary tremors commenced June 11, at 23h. 18m. G.M.T., and lasted for ten minutes. Violent oscillations then commenced suddenly, and lasted to June 12, 0h. 33m., after which slighter tremors



continued up to 1h. 12m. The oscillations can be traced fully six times the measure of sensitiveness of the instrument on one side of the normal line, and four times on the other, which are together equivalent to a tilt of the supporting frame of about twenty seconds of arc. I enclose a negative of the original photograph, which, however, does not show all the minor details of the effect produced. THOMAS HEATH.

Royal Observatory, Edinburgh, June 15.

Subjective Transformations of Colour.

MR. SHELFORD BIDWELL'S experiments, described in NATURE of June 10 (p. 128), remind me of a phenomenon which can be very easily demonstrated.

A disc is arranged so that a small sector, about one-sixth, is of a bright colour, while the remaining portion is white. If this be rotated slowly, the coloured sector appears to be followed by a ghost of the complementary colour: on quickening the rotation, *the original colour is lost, and the whole disc appears to be of the complementary colour*: but if the rotation be further quickened until flickering ceases, the original colour again predominates. In this way emerald-green may appear to change to pink, or crimson-lake to green.

This seems to be another instance in which the negative after-sensation is stronger than the original sensation. For the success of the experiment it is probably necessary so to adjust the rotation that (*a*) the negative sensation has a longer duration than the original sensation, and (*b*) the next original stimulus shall follow before the after-sensation has entirely faded. If the rotation be too rapid, the negative sensation has not time to develop, and only the original colour is seen.

Mason College, June 12. F. J. ALLEN.

Planetary Orbits, illustrated by a Rolling Ball.

THE interesting article in NATURE, April 29, by R. W. Wood, on the orbits of a steel ball about a magnet pole, suggests to me that it may interest some of your readers to hear of another plan for showing these orbits, which, but for the slight resistance of the air, is very nearly theoretically accurate, and in which the proper initial velocities are easily produced.

The plan consists of causing a true steel ball—of, say, one inch or more in diameter—to roll on a hard and smooth surface of the proper form. The surface on which the *centre* of the ball moves is formed by the revolution of a part of a rectangular hyperbola about a vertical asymptote, and the real surface on which the ball rolls is, of course, a distance equal to the radius of the ball from this imaginary surface at all points.

Fig. 1 is a vertical section, on a very small scale, in which the dotted lines show the rectangular hyperbola and its vertical and horizontal asymptotes, and the full curved lines show the actual surface on which the ball rolls; the interval between the dotted and full curved lines being equal to the radius of the ball.

FIG. 1.

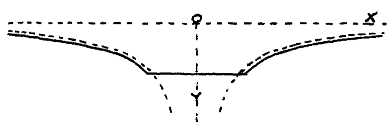


FIG. 2

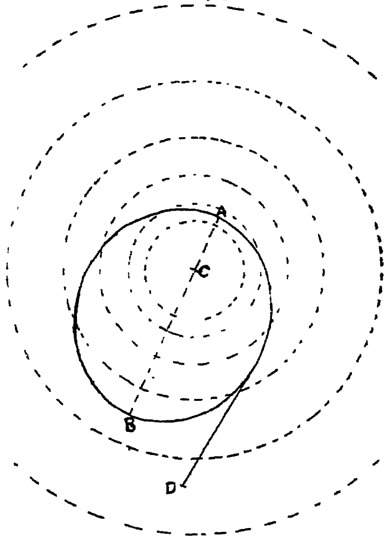

Fig. 2 is a projection on a horizontal plane showing contours of the hyperbolic surface at equal vertical intervals in dotted lines, and also one of the orbits referred to below in full lines.

Suppose the ball to be allowed to roll from the level of the horizontal asymptote, and directed so as not to come too near the centre (C) of the surface, it will describe a path whose projection on a horizontal plane is very nearly a parabola; and—as in the imaginary case of a comet coming from an infinite distance without initial velocity—its energy will be accurately in the inverse proportion to its horizontal distance from the centre of attraction, because the reciprocal of its distance from the centre is proportional to the vertical distance it has fallen, by the well-known property of the rectangular hyperbola. If the ball be allowed to roll from a point higher than the horizontal asymptote, it will describe a hyperbola; and if from a lower point, an ellipse.

To produce an ellipse having any given axis-major as A B, Fig. 2, let the ball roll from a point D, on the hyperbolic surface, whose distance from the centre C is equal to A B, and let it be directed with a straight-edge till it touches the desired orbit.

If we could neglect the resistance of the air and all other small resistances to the rolling of the ball, the actual energy, and therefore the velocity of the ball would be precisely what they ought to be to illustrate planetary motion; the direction of motion not being generally horizontal, however, and the orbit not exactly in one plane.

The fact that a part of a rolling ball's energy is rotational and part translational does not vitiate the experiment, because the proportion of the one part of the energy to the other remains constant.

In the case of a steel ball attracted by a magnet pole, the acceleration would appear to be inversely as some higher power of the distance than the square. In the case explained above, the acceleration is very nearly inversely as the square of the horizontal distance from the centre, and only differs from this proportion in being less, as the actual distance traversed by the ball exceeds its horizontal component, at any point; which may be a very small percentage. GEO. ROMANES.

Craigknowe, Slateford, Midlothian.

THE APPROACHING TOTAL ECLIPSE OF THE SUN.[1]

II.

THE considerations which led me, in 1871, to employ a spectroscope without collimator may here again be summarised. If in an ordinary spectroscope, the straight slit be replaced by a circular one, bright rings replace the bright lines which are ordinarily seen in radiation spectra, and since in the solar surroundings we have chiefly to deal with radiation phenomena, the chromosphere and corona themselves can be used during an eclipse as ring slits, and on account of their distance, a collimating lens can be dispensed with.

In the report on the eclipse of 1875, by Dr. Schuster and myself, the principles of the method, as applying to photographs taken during totality, were stated as follows (*Phil. Trans.*, 1878, Part 1, p. 139):—

"Supposing that the corona and chromosphere only send out the same homogeneous light, one image only will appear on the sensitive plate, the only effect of the prism being to displace the image. As far as the protuberances are concerned we know they give a spectrum of bright lines, and we expect, therefore, to find on the plate each protuberance represented as many times as it contains lines in the photographic region. The different protuberances would be arranged in a circle round the sun, and these circles would overlap or not, according to the dispersive power of the prism and the difference in refrangibility of the lines. . . . If the corona gives a series of bright lines we shall find a series of outlines on the photographs similar to that corresponding to the protuberances. . . . If we find that part of the corona gives a continuous spectrum, that part alone will be drawn out into a band."

To this it may be added, that successive photographs will differ on account of the difference of phase. One part of the chromosphere will be visible at the beginning of totality, and another part at the end. The smaller prominences visible at the beginning of totality are subsequently eclipsed by the moon, and their spectra are consequently absent from later photographs, while a new prominence region makes its appearance. In the same way, the part of the corona the spectrum of which is photographed will vary at different phases, but only in the lower parts.

The results obtained by Prof. Respighi and myself during the eclipse of 1871 in India, in which part of the attack consisted in the employment of slitless spectroscopes—a method of work at which we had arrived independently—indicated the extreme value of such observations.

For my own observations in 1871 I had arranged a train of five prisms without either collimator or observing telescope. "I saw four rings with projections defining the prominences. In brightness, C came first, then F, then G, and last of all 1474K. Further, the rings were nearly all the same thickness, certainly not more than 2′ high, and they were all enveloped in a band of continuous spectrum" (NATURE, vol. v. p. 218, 1872).

Respighi's observations were made with a telescope of 4½ inches aperture, with a large prism of small angle in front of the object-glass. The principal results obtained by him were as follows (NATURE, vol. v. p. 237, 1872):—

"At the very instant of totality, the field of the telescope exhibited a most astonishing spectacle. The chromosphere at the edge, which was the last to be eclipsed, . . . was reproduced in the four spectral lines, C, D_3, F and G, with extraordinary intensity of light. . . .

"Meanwhile the coloured zones of the corona became continually more strongly marked, one in the red corresponding with the line C, another in the green, probably coinciding with the line 1474 of Kirchhoff's scale, and a third in the blue perhaps coinciding with F."

"The green zone surrounding the disc of the moon was the brightest, the most uniform and the best defined."

My observation (Brit. Assoc. Report, 1872, p. 331) was made intermediately between the two observations of Prof. Respighi. The observations may be thus compared:—

Respighi	C	D_3 ...	F.G.	Chromosphere and prominences at beginning of totality.
Lockyer	C	1474 (faint)	F.G.	Corona 80 secs. after beginning of totality.
Respighi	C	1474 (strong)	F.	Later.

I had no object-glass to collect light, but I had more prisms to disperse it, so that with me the rings were not so high as those observed by Respighi, because I had not so much light to work with; but such as they were, I saw them better, because the continuous spectrum was more dispersed, and the rings (the images of the corona) therefore did not overlap. Hence, doubtless Respighi missed the violet ring which I saw; but both that and 1474 were very dim, while C shone out with marvellous brilliancy, and D_3 was absent.

In arranging for the eclipse of 1875 in Siam and the Nicobars, the method was further developed by the introduction of photography, and the first results of this extension were given in the Report of the Eclipse Expedition of that year. They showed clearly that with the rapid dry plates of to-day a considerable increase of dispersion might be attempted.

The object-glass employed on this occasion had an aperture of 3¾ inches and a focal length of 5 feet, while the prism had a refracting angle of 8 degrees.

Two photographs were obtained with exposures of one and two minutes respectively. Both are reproduced in the Report (*Phil. Trans.*, 1878, vol. clxix. Part i. p. 139), and they show only such differences as can be attributed to difference of phase. The dispersion was very small compared with the size of the sun's image, so that the photographs present the appearance of an ordinary photograph of the eclipsed sun, which is slightly distended in the direction of dispersion. The various prominences each show three images, two of which were identified with $H\beta$, $H\gamma$, while the others were found to correspond to a wave-length of about 3957.

It was suggested (Report, p. 149) that this represented the H and K radiations of calcium, and this is fully confirmed by the results obtained in 1893, to say nothing of results obtained in other eclipses.

I next proceed to remark very briefly upon the photographic results obtained since 1875. In 1878, near the sun-spot minimum, the method was employed by several observers, myself among them, but no *bright* rings were recorded. The maximum sun-spot conditions previously observed had entirely changed; indeed with a slit spectroscope the 1474 line was very feeble, and was only seen by a few of the observers, and hydrogen lines were similarly feeble (*American Journal of Science*, vol xvi. p. 243).

Part of my own equipment for this eclipse consisted of a small grating placed in front of an ordinary portrait camera, and with this I obtained a photograph showing only a very distinct continuous spectrum.[1]

The method was employed by Dr. Schuster in Egypt in 1882; the camera was of 3 inches aperture and 20 inches focal length, with a prism having a refracting angle of 60° (*Phil. Trans.*, vol. clxxv., 1884, p. 262). The single photograph obtained (not reproduced in the Report) was stated to show two rings, which were considered to be due to the lower parts of the corona, and therefore to correspond to true coronal light. The wave-

1 Continued from page 157.

1 With a duplicate grating I observed the spectrum of the eclipsed sun, and again in three different orders, saw nothing but continuous spectrum (NATURE, vol. xviii., 1878, p. 459).

length of one of these rings was measured to be 5315; it is due to the green corona line (1474K). The second was stated to be coincident with D_3.

In 1883 the same instrument used in Egypt in 1882 was employed, as well as a 6-inch achromatic telescope, and a concave Rowland grating of 5 feet focus, arranged for taking ring spectra in the first and second orders.

It is stated in the Report (*Phil. Trans.*, 1889 A, vol. clxxx. p. 122) that the photographs "possess no features of interest," and neither reproductions, nor drawings nor measurements are given.

The prismatic camera employed in the eclipses of 1882 and 1883 was again used in the West Indies in 1886. Only the spectra of some prominences seem to have been recorded. There is no mention of rings. The hydrogen lines as well as K and *f* are noted (*Phil. Trans.*, 1889 A, vol. clxxx. p. 319).

While on the one hand the photographic results, to which reference has been made, certainly did not come up to the expectations raised by my observations of 1871; on the other, subsequent solar investigations confirmed my opinion that this was the best way of studying the lower parts of the sun's atmosphere, provided an instrument of much greater light-grasping power could be employed.

I determined, therefore, when arranging for the observations to be made during the eclipse of 1893, to renew the attack with the largest telescope and the greatest dispersion at my command.

The Solar Physics Committee was then in possession of a prismatic camera of 6 inches aperture. I decided, therefore, to employ it, all the more because the work on stellar spectra at Kensington had given abundant proof of its excellence.

The Eclipse of 1893.

The instrument was entrusted to Mr. Fowler, the demonstrator of astronomical physics in the Royal College of Science, who erected it at Fundium in West Africa, and obtained a series of photographs of the greatest value to science. A greater success has never been achieved in eclipse observations.

The object-glass of this instrument, corrected for the photographic rays, was constructed by the Brothers Henry. The correction is such that it is unnecessary to incline the back of the camera, and hence some of the objections which have been made to the use of this form of spectroscope are overcome. The large refracting angle of the prism (45°) obviously increases the value of the instrument for eclipse work.

The camera has a focal length of 7 feet 6 inches, and the spectrum obtained is about 2 inches long from F to K. Rings corresponding to the inner corona are about seven-eighths of an inch in diameter.

The tube is a strong mahogany one, square in section, and it was attached to the declination axis by means of a suitable iron plate. In order to reduce the weight of the instrumental equipment, the heavy iron pillar of the equatorial was replaced by a rough wooden stand which was filled up with concrete after being placed in position. Provision was made for the clock bracket and fine adjustments of the polar axis, and the whole arrangement was quite satisfactory.

Fig. 7 represents the instrument as adjusted for use in latitude 14° 3' N. When actually at work, the camera was steadied by a stiff wooden rod screwed to the end of the tube, and bearing on the end of the declination axis; this did not interfere with the driving gear and materially contributed to the successful results, as on account of the great weight of the prism it was necessary to bring a large part of the tube forward to the eye end. The brass cap which protected the camera from light other than that which passed through the prism and object-glass, is not shown in the diagram.

As time is very precious during an eclipse, every effort must be made to economise it. I may therefore refer to the manner in which the photographic operations were facilitated by the dark slides used.

The construction of the camera and dark slides, or plate-holders, was based on the plan which I devised for the large pictures of the corona which I hoped to obtain in the West Indies in 1886. The slides are about 13 inches in length by 7 inches broad, and have three compartments, each taking a plate 6 inches by 4 inches.

The camera at the end of the long wooden tube has an opening 6 inches square, and a rectangular frame 24 inches long, with a central aperture 6 inches by 4 inches, and provided with grooves to take the slides, was symmetrically attached to it. A dark slide being placed in the frame, so that the first compartment was opposite the middle of the telescope tube, the shutter was then opened to its full extent, and an exposure made; the plate in the second compartment was next brought to the middle of the frame, by pushing the slide along, and also exposed; again, by moving the slide along, the third plate was brought into position and exposed, after which the shutter was closed and the slide withdrawn. During the exposure of any one of the three plates in a slide, the other two were protected from light by the rectangular frame.

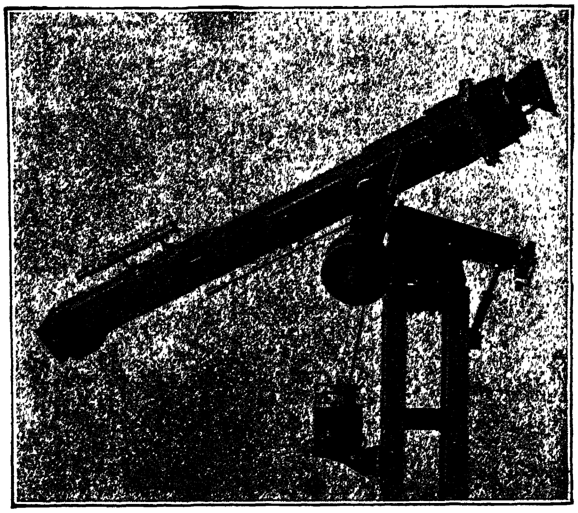

FIG. 7.—The 6-inch prismatic camera arranged for work during the Eclipse of 1893.

The upper edge of each dark slide was notched in three places corresponding to the positions of the three plates which it contained, and, as each plate came to the proper position for exposure, as the slide was pushed along, a spring catch automatically dropped into its place.

Upon the back of each dark slide six numbers were painted in clear white figures. A small series of numbers corresponded to the numbering of the thirty plates to be exposed during the eclipse, and a larger series indicated the exposures to be given to each plate, so that it was unnecessary to refer to any list.

These time-saving devices are of the highest importance in eclipse work, and too much attention cannot be given to them. The arrangements in West Africa worked admirably, and it was possible to change from one plate to another in about a second when a slide was once inserted, and to change the whole slide in five seconds. Longer intervals, however, were allowed to elapse between the exposures, in order that the instrument might steady itself, and to correct the backlash of the driving screw.

The instrument was focussed by photographing the spectra of some of the brighter stars. This is the only satisfactory method of focussing the prismatic camera, as rays from a star fall on the prism under exactly the same conditions as those from the eclipsed sun. If a slit and collimator be employed, identical conditions can only be obtained when the collimator is perfectly achromatic and absolutely adjusted for parallel rays.

FIG. 8.—Untouched reproduction of photograph (African station) taken very shortly after the commencement of totality, the exposure being "instantaneous." At this phase of the eclipse a considerable arc of the chromosphere was visible, and its spectrum is therefore shown in addition to the spectrum of the higher reaches of some of the large prominences extending beyond the moon's limb. It will be seen that at H and K there are long arcs of chromosphere and prominences, the absent portions being of course obscured by the moon. One very small prominence is especially rich in lines.

I next come to the kind of result obtained by means of the unprecedented optical power employed in 1893, and for this purpose I reproduce two of the beautiful photographs obtained by Mr. Fowler.

It will be seen that we get more or less complete rings when we are dealing with an extended arc of the chromosphere, or lines of dots when any small part of it is being subjected to a disturbance which increases the temperature, and possibly the number of the different vapours present.

The interpretation of these photographs brings us in presence of many interesting and, at the same time, complicated problems. I cannot, however, refer to them

FIG. 9.—Photograph 21 (African station), taken shortly before the end of totality. A portion of the chromosphere on the other edge of the dark moon is now visible in addition to numerous prominences. It will be seen that one of the smallest prominences is rich in lines, and closely resembles that which appears in Fig. 8.

here. I have set them out at length in the *Phil. Trans.* (vol. for 1896 A, p. 551).

The instrument so successfully employed by Mr. Fowler was not the only one used in 1893. I had been able to equip Mr. Shackleton, one of the computers attached to the Solar Physics Observatory,

with a large photographic spectroscope, deprived of its collimator, for use in Brazil. In this instrument we had two prisms of 60°. The object-glass was a Dallmeyer portrait lens 5D, aperture 3·25 inches, with a focal length of 19 inches. With this he was able to secure a second series of photographs.

The most important results recorded in 1893 may be stated as follows. We not only determined the wave-lengths with considerable accuracy of some 400 lines in the spectra of the chromosphere and prominences, and studied the distribution of the gases and vapour which gave rise to them, but the separation of the spectrum of the corona from that of the chromosphere was made perfectly clear. J. NORMAN LOCKYER.

(*To be continued.*)

WORK AND PROGRESS OF THE GEOLOGICAL SURVEY.[1]

THE first remark that will naturally occur to a geologist into whose hands this Report may come, will probably be one of satisfaction that the account of the work of the Geological Survey for the past year should have been brought out so early, and in a separate form in which the public can purchase it at a low price. But his pleasant surprise will soon be changed into feelings of another kind when he opens the volume and finds it printed, as heretofore, on poor, flimsy paper and in small, close type, so that the perusal of its pages becomes wearisome to the eyes. There could hardly be a stronger contrast to this style of production than that in which the Reports of the United States Geological Survey are issued. These, alike in paper, type and printing, are truly sumptuous publications placed alongside of the miserable efforts of our Stationery Office. Even Canada can afford to present the Reports of its Geological Survey in a form that should make our authorities blush. It is lamentable to see so much excellent scientific work offered to the world in such miserable guise. The Canadian Reports are not only better printed on better paper than ours, but they are actually sold at cheaper rates. Why cannot the mother-country afford to keep up to the level of her transatlantic colony?

The present Annual Report of the Director-General is the longest and most detailed which he has yet issued. It presents a clear picture of the activity of the Geological Survey over all the fields on which the staff is engaged, and enables the public to follow intelligently the progress of the work in the three kingdoms. The volume, or pamphlet of rather more than 100 pages, is divided into three sections, one dealing with the Geological Survey itself, one with the Palæontological Department, and one with the Museum of Practical Geology in Jermyn-street. The section that treats of the Survey consists of two portions, the first of which is devoted to the general statistics and administration of the three branches of the service in England, Scotland, and Ireland. It is interesting to notice in this, as in former Reports, the large extent to which the work of the Geological Survey is made use of for practical purposes. In different ways geology affords valuable information with regard to water-supply, reservoirs, drainage, soils, lines of railway, sites of houses, nature of building materials, and many other questions of daily life. The offices of the Geological Survey have become the recognised headquarters for information of this nature respecting the British Islands. The various Government Departments apply freely for assistance and advice, while the general public continues to make daily inquiries in regard to matters which involve a practical knowledge of geology.

[1] Annual Report of the Director-General of the Geological Survey of the United Kingdom for 1896. London: Printed for her Majesty's Stationery Office, 1897. Price 6*d*.

The scientific results obtained by the Survey during the past year occupy the greater part of the Report, and are full of interest. The narrative of them is arranged in stratigraphical order, beginning with the oldest rocks. We are first taken into the district of Charnwood Forest, and shown the excellent work done there recently by Mr. W. W. Watts. We are then transported into the north-west of Scotland, and watch the labours of Messrs. Peach, Horne, and Clough among the mountains of Assynt and the hills of Skye. The wonderfully complex structure of the country between Cape Wrath and the southern promontory of Skye has now been worked out in detail, most of the maps of that region are published, and we may before long expect a full account of the whole belt of complication from the able band of surveyors who, amidst all the inclemencies of that boisterous climate, and all the physical difficulties of rugged mountain and shaking bog, have so skilfully unravelled the details of one of the most interesting and difficult geological districts in Europe.

In the northern, central and southern Highlands satisfactory progress continues to be made. In the far north Mr. Horne and Mr. Gunn have been at work among the "Moine schists" of Sutherland and Ross-shire. Mr. Barrow and Mr. Cunningham Craig are to be found among the glens and corries of the higher Grampians. Mr. Hinxman is busy among the rocks of Strathspey. On the west side of the country a chain of observers is stationed from the flanks of Ben Nevis to Loch Awe and the hills of Lorne. Mr. Grant Wilson is engaged among the schists and limestones of Loch Linnhe. Mr. Hill has continued his investigation of the metamorphic series around Loch Awe. Mr. Symes has made progress with the volcanic district of western Argyllshire; while Mr. Kynaston has been laying bare the secrets of Ben Cruachan. The work of each of these investigators is succinctly summarised by the Director-General, and attention is called to the more important results obtained in the examination of the younger or Dalradian schists of the Highlands. The mapping is likewise in progress among the metamorphic rocks of the Western Isles, Mr. Wilkinson having now completed the survey of Islay; while Mr. Gunn is prosecuting that of Arran.

One of the most important problems now engaging the attention of the Survey in the Scottish Highlands is connected with the position and relations of a belt of comparatively unaltered strata, wedged in between the schistose rocks and the Old Red Sandstone which has been faulted down against them. These strata, from their lithological characters, their sequence, and their including certain radiolarian cherts, are regarded as probably the equivalents of the closely similar rocks which lie in the Arenig division of the Silurian rocks of the Southern Uplands of Scotland. If such should eventually be proved to be their true age, they will have an important bearing on the age of at least the latest movements to which the Highland rocks owe their contorted and puckered structure. The problem, however, seems to become more difficult the longer it is studied. Last year Mr. Clough, who is engaged on its investigation, has found that no satisfactory line can be drawn between the presumably Lower Silurian strata and the general mass of the rocks of the southern Highlands. If any portion of these rocks should prove to be of Palæozoic age, it would be a notable discovery in British geology. In the meantime we must patiently await the result of the continuation of further research along the Highland border.

The mapping of the Cambrian rocks of the north-west of Scotland has now been completed by the surveys in Skye made last year by Mr. Clough. One of the most singular features of these ancient deposits is the persistence of the same lithological bands for a distance of

100 miles from the mouth of Loch Eriboll into Sleat in Skye. Not only the bands of the Durness limestone, but the "fucoid beds" and the marked subdivisions of the underlying quartzite retain their general characters throughout the whole extent of their outcrop.

The mapping of the Isle of Man has now been completed by Mr. Lamplugh. Much information has been obtained as to the structure of the "Skiddaw Slates" of that island, but no further evidence has been found to fix their true geological age.

The revision of the Silurian formations of the Southern Uplands of Scotland has been brought to a close by Messrs. Peach and Horne, with the assistance of Mr. A. Macconochie. The whole complicated structure of that extensive region has now been unravelled. Among the more interesting recent additions made by these observers to our knowledge of the ground, has been the wide development of volcanic rocks associated with the Lower Silurian sediments. The chief interval of volcanic activity seems to have been the Arenig period; but last year evidence was met with of contemporaneous lavas in the Bala series of Peebleshire. In the Report some valuable details are supplied by Mr. Teall regarding the volcanic series of the Southern Uplands, and also the Galloway granites with their apophyses and attendant metamorphism.

The Silurian areas of Ireland are likewise undergoing revision, with the view of bringing the maps up to the present state of knowledge on the subject. The whole of the country north of Dublin has now been completed by Messrs. Egan and McHenry; while the fossil collector, Mr. Clark, has discovered many new localities for fossils in the Silurian rocks. The revision proceeds upon a careful search for organic remains, and the subdivisions of the Silurian formations are based essentially on the evidence of these remains.

Some important modifications of previously published views were obtained last year by Sir Archibald Geikie and Mr. Kilroe in the west of South Mayo and North Galway. Evidence was gathered which showed that the volcanic rocks of that region, hitherto regarded as of Upper Silurian age, undoubtedly belong to the lower division of the system.

In the Old Red Sandstone, the chief work accomplished by the Survey in 1896 lay in Ross-shire, Arran, and Argyllshire. In the first-named country two hitherto unknown outliers of this formation, capping hills of schist, were found by Mr. Gunn—striking monuments of the denudation of that region. In Lorne considerable progress has been made in the mapping of the interesting volcanic series of the Old Red Sandstone, and some suggestive observations have been made by Mr. Kynaston as to the possible connection of the andesite lavas with the granite of Ben Cruachan.

Among the Carboniferous rocks, the chief task on which the Survey is at present engaged is the revision of the coal-fields on the scale of six inches to a mile. Good progress is reported in the mapping of the great coal-field of South Wales, and a beginning has now been made with the publication of the re-survey. The new maps cannot fail to be of great value in the future development of the mineral resources of this important region. In general, each coal-owner knows only his own ground, and that often very imperfectly. No general acquaintance with the structure and resources of the whole coal-field can be obtained until all the scattered observations at the different mines are correlated and generalised. This, however, is a result which could hardly be effected by private enterprise. It is essentially a national undertaking, and it is this task on which the Geological Survey is now engaged. Mr. Strahan and his colleagues, who are charged with the re-survey, are to be congratulated on the excellent maps which they are producing. Not only are the Coal-measures receiving attention, but the surrounding older formations, the mapping of which is required for the completion of the sheets of the coal-field, are undergoing careful examination, and have already yielded some interesting new results. Thus Mr. Strahan last year discovered that the igneous rocks, which have long been supposed to be intrusive in the Carboniferous Limestone of West Somerset, really include intercalated tuffs, marking the sites of volcanic eruptions during Carboniferous time in the south-west of England.

Strata of Permian age are reported from the northern end of the Isle of Man, where they have been detected in some unsuccessful borings for coal. The younger red sandstones of the Isle of Arran are regarded as not improbably belonging to the same geological system.

Triassic and Rhætic rocks have been mapped over considerable tracts along the southern side of the South Welsh coal-field, and some interesting data have been obtained by Mr. Cantrill regarding the nature and origin of the breccias lying at the local base of these formations.

The most important area of Jurassic rocks examined last year lies in the district of Strath, in Skye, where the ground was mapped by Mr. H. B. Woodward, who has traced the lithological and palæontological subdivisions of the Lower and Middle Lias.

The Cretaceous system over considerable tracts of the south of England was examined during the past year for the purpose of mapping its subdivisions, the clear delineation of which is now found to have so important a bearing in questions of water-supply. Mr. Jukes Browne is engaged on the preparation of a general memoir on the Upper Cretaceous formations, and has had much assistance from Mr. William Hill, whose extensive and accurate knowledge of the subject has been placed at the service of the Survey.

The field-work in the south of England during 1896 lay, for the most part, outside of the areas of the Tertiary formations. Most of the mapping among rocks of that series was carried on in the west of Scotland, where so large and varied a development of Tertiary igneous masses occurs. Mr. Harker continued his investigation of the eruptive rocks of Skye, and contributes some important facts to the Annual Report. Mr. Hinxman noted two remarkable vents in Raasay, while Mr. Gunn was successful in adding a number of previous unknown particulars to our knowledge of the younger igneous rocks of Arran.

The Superficial Deposits, formerly entirely neglected, now receive a large share of the attention of the Geological Survey. As they thickly cover wide tracts of country, they are of paramount importance in regard to agriculture, water-supply, drainage and many other questions of daily life. It is most desirable, therefore, that their nature and limits should be accurately delineated upon maps. This has been done by the Survey over the whole of the northern half of England, and the same investigation is now in progress in the southern half. When the "Drift Survey," as it is called, is completed, the British Isles will be in possession of a map which will serve as an admirable guide to the farmer, well-sinker, engineer, and generally to the whole of that wide public that is practically interested in the relation of the soils and subsoils to all kinds of sanitary questions.

The Survey, while dealing with these applications of its work, does not lose sight of the intensely interesting geological problems presented by the various superficial formations. The present Report, like its predecessors, contains much fresh information on this subject. From the cwms of South Wales to the downs of Kent, the surveyors have been at work among the various drifts, and the more important of their observations are summarised by the Director-General. Of special interest are Mr. Lamplugh's generalisations regarding the successive stages in the history of the glaciation of the Isle

of Man, and Mr. Bennie's discovery of two ancient lake-bottoms near Edinburgh containing an arctic fauna and flora.

The Second Part of the Annual Report is devoted to the work of the Palæontological Department of the service, and contains a summary of the chief changes, additions and rearrangements made during the year in the palæontological galleries under the charge of Messrs. Sharman and Newton.

The general collections in the Museum form the subject of Part iii., wherein Mr. Rudler reports the principal events in the history of the Museum during 1896. It is satisfactory to observe that the collections continue to attract thousands of visitors, and that not only the general public, but schools, natural history societies, students' clubs, and individual students avail themselves of the admirable educational facilities afforded by the collections.

From what has here been said, it will be seen that the Annual Report of the Director-General of the Geological Survey is not a mere piece of dull statistics, but is an interesting and important contribution to science. It is a volume which will obviously be required in the library of every geologist, for it is crowded with observations which he will find nowhere else. Its publication as a separate work now places it within easy reach, and we trust that its sale will encourage Sir Archibald Geikie to continue the issue of as full a record in future years with perhaps, if the Stationery Office can be propitiated, diagrams illustrative of the more important facts described. In the meantime he and his able staff are to be congratulated on the appearance of so excellent a narrative of strenuous and successful labour.

STYLES OF THE CALENDAR.

AT the approach of the end of a century, this subject naturally comes to the front again; but it has lately been somewhat unexpectedly raised to special prominence by the suggested probability of one at least of the Oriental countries of Europe adopting the usage which, on the initiative of Rome in 1582, all the western nations gradually accepted, England (we say advisedly England *not* Britain, because Scotland adopted it before the union even of the crowns) being the last in 1752. America having been colonised by the western Europeans, and the United States having been still British colonies at the date last mentioned, the Gregorian style is universal in that continent. But eastern Europe, including Russia and all the nationalities of the Balkan peninsula, still adheres to the old Julian style; and this chiefly because the Christians of these countries belong to the Greek or Eastern Church, though it is difficult to see why this should restrain them from falling in with a change which has many conveniences, and would bring their dates into uniformity with those of the Latin, Teutonic, and Scandinavian nations—an object of increasing importance, as intercommunication is constantly becoming more frequent.

It is understood that for some time past, as the nineteenth century is drawing to its close, the question of a change has been discussed amongst the officials and astronomers of Russia; and that a plan was proposed to introduce it not by one operation, but gradually. Probably few persons amongst the general public reflect how essentially twofold the Gregorian alteration was; the object of making our calendar years correspond more accurately during the centuries with the tropical years of astronomers, so that the dates used should for all future time correspond with the equinoxes and other solar seasons, by no means implies the necessity of cancelling a number of days from the calendar so that these should correspond with what they were at some definite epoch in the past. The reason for this latter was purely ecclesiastical, the purpose being that, in celebrating Easter, the full moon following the vernal equinox should be governed by one bearing the same date as it did at the time of the Council of Nicæa. This the Eastern Church appears to have thought of less consequence than did the Western; and, indeed, it cannot be proved that on this point the Council did more than decree, in opposition to the so-called Quartodecimans, that Easter Day should always be kept on a Sunday. However that be, when it was noticed that the vernal equinox (which in the time of Julius Cæsar fell on the 25th of March, but in that of the Council A.D. 325, on the 21st), the question was from time to time agitated at Rome of effecting a change in the Julian reckoning. In passing it may be mentioned that Cæsar and Sosigenes the Alexandrian, who assisted him, were quite aware that the true length of the year was somewhat less than $365\frac{1}{4}$ days; the important point of the alteration of the calendar then carried out, was the abolition of the former cumbrous system of the Romans by combining a solar and lunar chronology with intercalary months, which were constantly falling into confusion, and the adoption of one wholly solar, the months being made artificial divisions, and it being thought that (the *exact* length of a year being not known) the regular introduction of an additional day every fourth year (making what we call a leap-year) would be quite sufficient for all practical purposes. Pope Sixtus IV. seriously took in hand the question of improving the Julian system, and in consequence of the great reputation of Regiomontanus (as he is commonly called from his birth-place, though his real name was Müller), who was making observations with his friend Walther at an observatory, the first ever made in Europe, erected by the latter at Nürnberg, sent for him to Rome to assist in this object, but, unfortunately, Müller died shortly after his arrival in 1476, which was about three years after the birth of Copernicus. The scheme was therefore again delayed, and was finally executed under the authority of Gregory XIII. in 1582. A century earlier it would have been adopted throughout western Christendom; as it was, the Protestant countries were slow to follow it, and some of the German States at first endeavoured to make some modifications by using a true instead of a calendar full moon, which did not work well in practice, because the moon is not necessarily full on the same day in different localities. England adopted the Gregorian style in its entirety (already, as we have said, used in Scotland), chiefly at the instance of Lord Chesterfield in 1752; and long before the end of last century the same rule was observed over western Europe, no further alteration having been made since, though it has often been noticed that even the Gregorian year is not absolutely accurate.

A definite proposal is now being made in one of the smaller eastern States for the abandonment of the Julian reckoning still observed by them, and the adoption of the Gregorian style. In the *Times* of the 11th inst., Signor Cesare Tondini de Quarenghi informs English readers that he has drawn up a Bill at the request of the Bulgarian Prime Minister, M. Stoiloff, to be shortly laid before the Sobranye for the purpose of effecting this change in Bulgaria; and he also states that he has been informed that Russia is desirous that this example should be thus set before being carried out in that country. How that may be, we are not in a position to know, but it is surely desirable (though even astronomers are not unanimous on the point) that the year should correspond on the whole, and as far as practicable, with its true length, whilst uniformity of usage throughout Christendom, would undoubtedly be a gain of convenience. We would fain hope that some international agreement might be come to by which, after the dropping of a leap-year in 1900, its regular omission at the end of each period of 128 years should be arranged. This would be a more

accurate rule than the Gregorian; and as by either 2000 would be a leap-year, the difference would first show itself in 2028, which, according to this arrangement, would not be a leap-year, whilst by the Gregorian scheme the next omitted leap-year would be 2100. The omission of a leap-year at the end of each period of 128 years was advocated, it may be mentioned, by Sir E. Beckett Denison (now Lord Grimthorpe) in his "Astronomy without Mathematics," and by the present writer in the "Companion to the British Almanac for 1882." Its accuracy may easily be shown. It signifies having 31 instead of 32 leap-years of 366 days in 128 years, and therefore 97 common years of 365 days. Now $365 \times 97 + 366 \times 31 = 46{,}751$, which, divided by 128, gives 365·2422, the actual length of a tropical year to the fourth decimal. We cannot close without expressing a further wish that some agreement may hereafter be come to amongst Christian nations to celebrate Easter also according to an exclusively solar chronology, by observing it on the first or second Sunday in April. That, however, is independent of the plan now proposed in Bulgaria to abandon the Julian style of the calendar.

W. T. LYNN.

GRANTS TO UNIVERSITY COLLEGES.

IN accordance with an undertaking given by the Chancellor of the Exchequer to a deputation which waited upon him at the end of 1895, with reference to increased aid from public funds for the University colleges, three gentlemen, viz. Mr. T. H. Warren (President of Magdalen College, Oxford), Prof. D. G. Liveing, F.R.S., and Mr. Robert Chalmers, of the Treasury, were appointed in March 1896 to visit the colleges sharing in the grant made to universities and colleges in Great Britain, and to investigate the character and quality of university work done, as well as to inquire generally into the position which each college occupied both financially and in other respects The visits were concluded by the end of last year, and the report came before the Lords of the Treasury about two months ago. The results of the inquiry showed the Chancellor of the Exchequer that a case had been made out for asking Parliament to increase the sum to the colleges sharing in the grant; he therefore recommended that the total grant to the colleges should be increased from 15,000*l*. to 25,000*l*. as from April 1, 1897. The question of the apportionment of this total sum was thereupon referred to a special Committee, whose recommendations, as will be seen from the subjoined Treasury Minute, have been accepted:—

My Lords read the report of the 20th ult. from the Committee appointed by the Treasury Minute of April 5 last to advise this Board in the matter of the apportionment of the increased sum of 25,000*l*. which Parliament has been asked to vote in the current financial year for University colleges in Great Britain.

My Lords accept the apportionment which the Committee propose, viz.:—

The Owens College, Manchester	£3500
University College, London	3000
University College, Liverpool	3000
Mason College, Birmingham	2700
King's College, London	2200
Yorkshire College, Leeds	2200
Durham College of Science	2200
University College, Nottingham	1500
Firth College, Sheffield	1300
University College, Bristol	1200
Bedford College, London	1200
	£24,000
University College, Dundee	1000
Total	£25,000

In deference to the express recommendation of the Committee, my Lords have consented to grant to the Owens College, Manchester, a sum in excess of the *maximum* of 3000*l*. specified in the Board's Minute of April 5, 1897. They desire, however, to make it clear that this increase is made solely in recognition of the pre-eminence of the Owens College, and must not be construed as a precedent for increasing the grant of any other college beyond the normal *maximum*.

My Lords take note of the term of the Committee's report with regard to the Dundee College. In acceding to the Committee's recommendation that "for the present" the college should receive 1000*l*. a year, my Lords are guided, as they understand the Committee to have been guided, by the exceptional position in which the college is now placed with regard to St. Andrews University. My Lords, however, are of opinion that, when the relations between the University and the college are settled, this matter should be subject to reconsideration; and they must not be understood to admit the claim of the college to share permanently in the grant to University colleges.

The Board accept, so far as they are concerned, the recommendation that, with the exception of Dundee College, the above allocation should be settled for a term of five years from April 1, 1897. They also agree that before the end of such term a further inspection should be made on behalf of the Treasury.

My Lords will communicate to the colleges concerned the Committee's recommendation in paragraph 6 of their report that, in certain cases, three-fourths of the additions to the several grants should be devoted to staff purposes.

The future inspection, as recommended by the Committee, should extend to the University Extension colleges at Reading and Exeter, as also to the Hartley Institute at Southampton, and to any other college which, being located in a populous district, may claim to be treated as a fully-equipped college in arts and science.

The Chancellor of the Exchequer invites the Board to consider the qualifications, other than educational, which should be required from a college seeking to share in the grant in future. The Chancellor of the Exchequer submits to the Board that public money should not be contributed to a college which is still in the experimental stage or which has not yet succeeded, though fully equipped, in attracting a considerable number of students in arts and science. He therefore recommends that the financial conditions of participation should be—(1) A total local income for arts and science of at least 4000*l*. a year; and (2) a receipt from fees in the same subjects of at least 1500*l*. a year.

My Lords approve. It only remains for them to record their appreciation of the valuable services which the Committee has been so good as to render to this Board in considering the claims of the respective colleges.

HONOURS FOR MEN OF SCIENCE.

THE honours list issued on Tuesday in connection with the Diamond Jubilee contains the names of a number of men of science upon whom her Majesty has been pleased to confer distinctions.

Dealing first with Fellows of the Royal Society, Mr. Crookes and Dr. Gowers receive knighthoods. In the order of the Bath, Mr. Wolfe Barry, President of the Institution of Civil Engineers, Dr. Frankland, Foreign Secretary of the Royal Society, Dr. Huggins, Mr. Norman Lockyer, Director of the Solar Physics Observatory, Dr. Thorne Thorne, Principal Medical Officer to the Local Government Board, and (naval promotion) Admiral Wharton, Hydrographer of the Admiralty, are appointed K.C.B.

Mr. Christie, Astronomer Royal, and Mr. Niven, Director of Studies at the Royal Naval College, are appointed C.B.

In the Order of the Star of India, Sir Joseph Hooker and Lieut.-General Strachey are promoted to the grade of G.C.S.I.

In addition to the foregoing, Baronetcies are conferred upon Sir Wm. MacCormac, President of the Royal College of Surgeons; Mr. Wilks, President of the Royal College of Physicians; and Mr. Thomas Smith, Surgeon-Extraordinary to her Majesty. Mr. Durston, Engineer-in-Chief to the Navy, is made a K.C.B., and knighthoods are conferred upon Mr. A. R. Binnie, the Engineer to the London County Council, and Dr. Felix Semon.

NOTES.

THE preliminary programme of the International Congress of Mathematicians, to be held at Zürich on August 9-11, has just been issued. The first general meeting of the congress will be held at nine o'clock on the morning of Monday, August 9, in the Aula of the Zurich Polytechnicum. M. Poincaré will commence the proceedings with a paper on the relation between pure analysis and mathematical physics. The next item on the programme is a report of the committee on the object and organisation of the congress; and this will be followed by a paper, by Prof. Dr. A. Hurwitz, on a development of the general theory of analytical functions. The afternoon and evening of Monday will be given to a banquet, a river excursion, and a soirée. On Tuesday, August 10, the congress will meet at 8 a.m. in six different sections, dealing respectively with papers on algebra and theory of numbers, analysis and theory of functions, geometry, mechanics and mathematical physics, astronomy and geodesy, history and bibliography. On Wednesday, August 11, the second general meeting will be held. The organisation of mathematical congresses will then be discussed, and the date and place of the next meeting will be decided upon. On the same day an address will be given by Prof. F. Klein, on the question of higher mathematical instruction, and one by Prof. G. Peano, of Turin, on "Logica mathematica." It is requested that mathematicians who propose to take part in the congress will communicate with Prof. Dr. A. Hurwitz, Falkengasse 15, Zürich, before August 1. A ladies' committee has been formed to look after the comforts of lady visitors while the congress is in session.

PARTICULARS of the construction of the wonderful steam-turbine-driven boat—the *Turbinia*—designed and built by the Hon. C. A. Parsons, were given in NATURE three weeks ago (p. 116). We understand that the *Turbinia* steamed to Cowes last week, stopping at Harwich, without the smallest hitch. On this long run without stop, the complete absence of vibration was greatly appreciated by all on board; from Harwich to Cowes speeds of from sixteen to twenty-eight knots were maintained. The *Turbinia* will be at Cowes and in commission during the review week, for the inspection of visitors and the Press representatives. She is now capable of steaming between thirty-four and thirty-five knots.

THE elevating floor of the Yerkes Observatory at Chicago fell on May 29, just one week after the 40-inch lens had been placed in position. The drop was from its highest elevation, a distance of 45 feet. Fortunately the lens was uninjured, but repairs will take up the entire summer, and will delay the use of the telescope to that extent.

DR. S. A. PAPAVASILIOU has sent us an intimation that he has resigned the directorship of the Service géodynamique de l'Observatoire d'Athènes.

PROF. L. L. DYCHE, of the Kansas State University, has reached San Francisco, *en route* for Alaska, to make arrangements for an expedition to the Pole, beginning next season, and planned to extend over three years or more. He will have provisions for a five years' absence, making the start from the northernmost whaling station.

THE U.S. Secretary of Agriculture has designated a Board, of which Mr. B. Killen, of Oregon City, Ore., chairman of the Board of Regents of the Oregon Agricultural College, and Mr. Evans, of Washington, D.C., are members, to go to Alaska, to investigate the needs of an agricultural experiment station in that territory, and to secure data incident to the establishment of such an institution.

THE Cagnola prize of 2500 lire (100*l.*) and a gold medal having a value of 500 lire (20*l.*) was awarded to Prof. Dr. Ferdinando Sordelli last year for a memoir entitled, "Studi sulla Vegetazione di Lombardia durante i Tempi Geologici," which has just been published as volume xiv. of the *Atti della fondazione scientifica Cagnola.*

PROF. CHARLES L. BRISTOL, of the New York University, and three of his students, with Prof. Tarleton H. Bean, Superintendent of the Castle Garden Aquarium; Dr. W. M. Rankin, of Princeton, and Prof. Wm. H. Everett, of the New York University, sailed from New York for Bermuda on June 3, as a biological expedition. Besides collecting specimens, the party will try to discover a suitable site for a permanent station for the study of marine life. General Russell Sturgis has offered the University a site on his estate at Hamilton.

THE Commercial Museums at Philadelphia, containing industrial exhibits from all the nations of North and South America, including over 75,000 samples of natural produce and industrial products, was opened on June 2, by President McKinley, in the presence of many of the ambassadors of the different American countries, and of special delegates from others. The exhibition is the largest and most complete in many respects that has ever been held. An International Commercial Conference was held in connection with the opening of the museums, under the presidency of Dr. William Pepper, of Philadelphia.

THE United States Weather Bureau has been conducting experiments with kites flown at distances of from one to two miles above the earth, and now it is claimed that it is possible to forecast the weather for a period sixteen hours longer than at present, and more accurately. It is said that the fact has been established that shifting of the wind occurs at the height of a mile above the earth's surface from twelve to sixteen hours before the same change of direction occurs on the surface. Researches by means of high-flown kites and aeroplanes have now been prosecuted so far as to warrant the expectation that within six months the United States Weather Bureau will be able to construct a telegraphic synchronous chart based on conditions of the atmosphere one mile above the earth. This chart will cover the region between the Rockies and the Alleghanies at the outset.

A BOTANICAL society has recently been established at Perth, West Australia, and has been given the designation of the Mueller Botanic Society, as a tribute to the memory of the late Baron von Mueller, who spent the best part of his life in investigating the plants and other products of Australia. Sir John Forrest has been elected president of the new Society; Mr. Wittenoom and Mr. Leake, vice-presidents; and Mr. Skews, secretary.

FURTHER reports of the earthquake in India, on June 12, show that the disturbances were felt over a very extensive area. Considerable damage was done to public and private buildings at Calcutta, and many places in the provinces of Bengal and Assam have suffered very severely. The complete breakdown of telegraphs and other means of communication delayed the reports from Assam regarding the effects of the earthquake in that province. They are now, however, coming in, and present a terrible state of affairs. Reuter reports that at Shillong the shocks of earthquake were so severe and prolonged that everything was levelled with the ground, and many people lost their lives. Gauhati is in ruins. The roads are broken up into chasms, and the railway has disappeared, but no lives were lost. At Goalpara, on the Brahmaputra, the earthquake produced a wave of water which destroyed the bazaar and all pakka buildings. The country is covered with fissures, from which mud and sand are constantly spurting. At Dhubri all pakka buildings have been demolished. The river bank has subsided, the country is flooded, and the crops are ruined. Both at Goalpara and Dhubri there has been serious loss of life. Several places

are cut off from communication, and nothing has been heard from them. Throughout almost the whole of the province of Assam bridges have been destroyed and the roads rent with fissures, so that communication by road is impossible, and the telegraph cannot be used. Further information from Assam shows that the earthquake was slight in Silchar, Kohima, Manipur, Dilbrugarh, and Sibsagar; violent at Barpeta, Nowgong, and Mangaldai, in addition to the places already reported. The Chief Commissioner estimates the mortality from the earthquake in the Cherra Hills at between 4000 and 6000, but details have not yet been received.

THE semi-centennial anniversary of the American Medical Association, held at Philadelphia June 1–4, was attended by President McKinley. About 2500 delegates were present. Dr. Nicholas Senn, of Chicago, presided, and Dr. Nathan S. Davis, of the same city, founder of the Association, was also present. Several hundred papers were read before the various sections.

DR. ARTHUR G. BUTLER, writing in the *Zoologist* (June 15), describes some observations which tell against the assertion that birds build their nests by imitation, and that the reason why many of them at the commencement of the season trifle with building material for some time before they produce a satisfactory structure is that they are unable at once to remember exactly what the character of the nest was in which they first saw the light of day. Different hen canaries, reared in the usual square box of a London breeding-cage, were turned loose by Dr. Butler in aviaries in which no typical finch-like nest existed, and they reproduced nests nearly resembling those of their wild ancestors. A still more convincing proof of the instinctive building habit in birds is given. Dr. Butler turned loose a canary, also cage-bred, in one of his aviaries, late in April. The bird took possession of a square box hung high up on the wirework, and had almost completed a nest therein when it was disturbed. Afterwards it commenced and completed an elaborate cup-shaped nest in a dead bush.

WE are very glad to see that the value of experimental work in agriculture is becoming more widely recognised by British farmers. That this is so, is shown by a petition which agriculturists of the Dunblane district of West Perthshire have sent to the Board of Agriculture in favour of experimental farms. The petition points out that in the United States there are about fifty-four agricultural experimental stations, apart from colleges, receiving Government support to the extent of from 3000*l.* to 4000*l.* each; in France, Denmark, Norway and other countries, large sums are annually expended by Government in aid of agricultural education and research; and in Germany, about a dozen colleges and experimental stations combined receive an average Government grant of about 3000*l.* each. In comparison with this is the fact that in Great Britain the Government grants amount to only about 8000*l.*, which is distributed among eleven colleges and three dairy institutes, and is mostly expended on teaching. The petition goes on to state that a great deal of money is annually lost to farmers through the misapplication of manures, as well as by the injudicious feeding of stock; and though much knowledge has been accumulated by wise and observant farmers, yet this knowledge is being continually lost through want of proper record and confirmation. While some of the suggested remedies for agricultural distress are objectionable, it is believed that a judicious and extended system of experiment would tend, on the contrary, by teaching farmers how to grow larger crops with the same or less expenditure, to increase the supply of home-grown food without increasing its cost.

THE retirement of M. Folie from the directorship of the Brussels Observatory has led to an appeal in both Houses of the Belgian Parliament for the separation of the meteorological service from that of astronomy, which is now the case in nearly all other countries. *Ciel et Terre* of June 1 contains a verbatim account of the speeches made in favour of the separation. The Royal Observatory of Brussels was established in 1826 by A. Quetelet, who presided over the International Maritime Conference at that place in 1853, and whose works on the climate of Belgium, and the "Physics of the Globe" are still considered as models of scientific discussion. The Belgian Meteorological organisation, although dealing with a comparatively small area, is one of considerable importance in the European system. It issues a daily weather chart based upon the reports received by telegraph from nearly fifty inland and foreign stations, a volume referring specially to the observations made at the Observatory, by self-recording and other instruments, and a monthly *Bulletin* containing a summary of the observations made in the country. It supplies daily weather telegrams to the various fishing stations, and storm warnings, when necessary, based on the telegrams received from the Meteorological Office in London, and also issues notices to collieries in the event of unusual falls of the barometer.

MR. H. C. RUSSELL, C.M.G., F.R.S., sends us a description of a very brilliant aurora observed in lat. $47\frac{1}{2}°$ S., by Captain Hepworth, of the R.M.S. *Aorangi*, on April 20, while on a voyage from the Cape to Sydney. He thinks the aurora is by far the finest that has ever been seen in the southern hemisphere. It was first observed as a diffused light over the southern arc of the horizon at 6.30 p.m. From this light horizontal flashes soon spread, and flashed upward in every direction, increasing in length and brilliancy, until, at 7.30 p.m., they were shooting across the sky to within 30° of the northern horizon. At 8.30, Captain Hepworth noted that "an arch of bright green light, fading off into yellow, formed over the southern horizon, rose rapidly to a higher and higher altitude, and was followed by similar arches in regular sequence, until there were six distinct arches, their apices being from 10° above the southern horizon to 60° above the northern horizon. They were formed of vertical bands of light from 5° to 20° wide, bright green and yellow at their tops, and of a rosy hue at their bases. Subsequently these arches changed their shapes in all parts of the sky, others forming, but some kind of sinuous curve was always preserved, except in one or two cases. At 9 o'clock a circle formed round the zenith, having a rotary motion, this circular motion having been apparent in all the formations hitherto mentioned. A special feature in this display should be mentioned. These formations all had a westward movement. After 9.15 the aurora was less brilliant, but burst into greater activity a few minutes afterwards, more especially in the northern semicircle. The display lasted until 9.45, gradually fading after 9.30." Mr. Russell adds to this description some interesting remarks on the supposed connection between auroræ and the weather.

THE last number of the *Izvestia* of the Russian Geographical Society contains a dramatic account of M. Pastukhoff's second ascent of the Elbruz. The two summits of this Central Caucasus peak attain, as is known, the altitude of 18,470 feet and 18,340 feet respectively, and consist of two funnel-like craters, situated nearly two-thirds of a mile from each other. The northern and eastern slopes of the peak are covered with a thick *névé*, from which originate fourteen large and several smaller glaciers; they cover an aggregate surface of about sixty-seven square miles, and attain a great thickness, fissures 700 feet deep having been measured in one of them. The lowest level reached by the glaciers is 7640 feet. During the ascent, M. Pastukhoff's companion and one guide were disabled, and had to be left behind, and two nights had to be spent on the glacier,

under the protection of some stone blocks. While the Russian alpinist continued climbing, with one man only, a snowstorm overtook them; and though M. Pastukhoff reached the summit, he could only catch an occasional glimpse of the opposite border of the crater-like funnel, and leave there a tin box, with thermometers, under a big stone. The downward journey was terrible. M. Pastukhoff and his help lost their way, and when the night came they were on a glacier, which they could not identify, surrounded by a labyrinth of fissures. They had again to spend the night in a hole burrowed with their sticks in the snow, covered by one overcoat only, after having had no food all the day. Happily, next morning they fell in with the other guide, who had hastened to go down to a safer place as soon as the snowstorm began, and had carried with him a few biscuits. They soon found their way to the end of the Azau-glacier, where the other members of the party were anxiously waiting for their return.

THE Wellington Caves, situated in the vicinity of the town of Wellington, New South Wales, are remarkable for the large number of fossil remains of extinct animals found in them. The caves were discovered in 1830 by Sir Thomas L. Mitchell. The valley in which they are situated is bounded on each side by hills of limestone rock, rising to a height of about 100 feet on the eastern side, and considerably higher on the other. The floors of the caves are in places thickly covered with loose, dry, red earth which rises in fine dust at every step. At first it was anticipated that numerous fossils would be found in the earth, but after repeated digging only a few fragments of bone, apparently of the kangaroo, were obtained. About 80 feet to the west of the Great Cave is the Breccia Cave, one of the most important and interesting, from a scientific point of view, yet discovered in Australia. The floor is of red earth of considerable depth, the upper portion containing large numbers of bones. In this cave was found a skull, which proved to be the head of an enormous kangaroo. This led Owen to pronounce the opinion that there would be found the remains of a large carnivorous animal, which had been contemporary with the gigantic kangaroo, his view based upon the fact that the herb-eating marsupial must have had a natural enemy. This prediction was subsequently verified, for in 1887 a skull and several jawbones were found, the teeth being in an excellent state of preservation. These remains were ascertained to be those of a lion of a savage and carnivorous nature. It was also a marsupial, carrying its young in a kind of pouch. Other skulls of the animal have been found, but a complete skeleton has yet to be obtained. Mr. Gerard Krefft, who for several years was curator of the Sydney Museum, took much interest in the work of exploring the Breccia Cave, and under his superintendence many hundreds of fossil remains were recovered, not a few of which are now in the British Museum.

THE Superintendent of the National Zoological Park states, in the Smithsonian Report (1895) which has just been distributed, that a spontaneous outbreak of rabies occurred in one of the enclosures for foxes. This is interesting from a scientific point of view; especially as the animals were in perfect health, and, so far as is known, the disease could not have been introduced from without. A single case at first appeared, and this inoculated the entire cage of foxes, seven animals in all being lost. This curious phenomenon is of great interest as bearing upon the sporadic appearance of rabies in the dog.

MR. LAURENCE LAMBE, in a paper on the sponges of the Atlantic coast of Canada, which has just appeared in the *Transactions* of the Royal Society of Canada, gives a complete catalogue with descriptions of the marine sponges hitherto obtained from this coast and from the river and Gulf of St. Laurence. The list embraces thirty-one species, of which seven are new to science.

THE first of a series of contributions to Canadian botany, by Jas. M. Macoun, Assistant Botanist to the Geological Survey of Canada, appeared in vol. vi., No. 1, of the Canadian *Record of Science*, published January 1894. Ten of these papers have been published, the last in the number of the *Record of Science* which has just been issued. These contributions from the herbarium of the Geological Survey, form an addendum to Prof. Macoun's "Catalogue of Canadian Plants," the first part of which was published by the Survey in 1882, the last (Part vi.) in 1892. The first five parts, composing 1050 pages, include all the species of Phanerogams and Vascular Cryptogams known to occur in Canada, with their distribution. Part vi. deals with the Musci. The notes, which have from time to time appeared in the *Record of Science*, are records of species new to science or to Canada, and notable extensions of the known limits of species already recorded. As revisions of American orders and genera have been published, the necessary changes have been made in Canadian nomenclature, so that by means of the papers printed in the *Record of Science*, our knowledge of Canadian botany has been kept strictly up to date. Each of the ten papers already published averages about ten printed pages, with the exception of the last, which is about twice that size. Seventy-eight additions to the Canadian flora have been recorded in these notes, and the range of several hundred species has been greatly extended. They have been reprinted by the Geological Survey of Canada, and may be procured from the Librarian of that department at five cents per copy.

MR. T. H. HOLLAND, of the Indian Geological Survey, whose investigations of the Gohna landslip in 1894 had such successful results in the prevention of subsequent disasters, has now produced a detailed report on a similar subject. The hill-slopes about Naini Tal appear to be in some danger of slips, as in places the divisional planes of the slates dip in the same direction as the surface of the ground and at an angle which, though actually high enough to make slipping possible, is sometimes less than that of the hill-slope: such a condition is obviously extremely dangerous. The investigations include a full contour-survey and a geological mapping of the district, as well as a determination of the angle of repose for the various constituent rocks. The most dangerous sites are indicated, and suggestions for protective operations made where they are worth undertaking. A large number of plates illustrate the report, which is of importance, not only to the residents at Naini Tal, but to all interested in the general phenomena of landslips.

AMONG the articles and other publications which have come under our notice during the past few days, are the following:—Bog-bursts, with special reference to the recent disaster in Co. Kerry, by Mr. R. Lloyd Praeger, in the *Irish Naturalist* for June. Mr. Lloyd Praeger was a member of the Committee appointed by the Royal Dublin Society to investigate the bursting of the Knocknageeha bog in December last (see vol. lv. p. 254), and his paper is a summary, with illustrations of the observations made.—The presidential address, on "The Evidence for the Existence of Man in the Tertiary Period," delivered before the Geologists' Association at the last annual general meeting, by Mr. E. T. Newton, F.R.S., is printed in the May number of the Association's *Proceedings*.—"De verhouding van het gewicht der hersenen tot de grootte van het lichaam bij de zoogdieren," by Dr. Eugène Dubois. This paper, published by the Amsterdam Academy of Sciences (*Verhand. Kon. Akad. v. Wetensch.* Dl. V. No. 10, April), brings together and discusses a large number of observations of the relations between the weight of the brain and total weight of many animals.—The eighth contribution of "Materials for Flora of the Malayan Peninsula" is made to the *Journal* of the Asiatic Society of Bengal (vol. lxv., Part ii., No. 3, 1896), by Dr. George King, F.R.S., Superintendent of the Royal Botanic Garden, Calcutta.

—An interesting paper on early magnetic observations, "Die Anfänge der magnetischen Beobachtungen," contributed to the *Zeitschrift der Gesellschaft für Erdkunde* (vol. xxxii. part 2), by Prof. G. Hellmann, has been reprinted and is now published as a separate paper by W. H. Kuhl, Berlin.—Report on the progress of the Survey of Tides and Currents in Canadian Waters, by Mr. W. Bell Dawson. The report contains some valuable tidal data, and also the results of a general examination of the currents in the interior of the Gulf of St. Lawrence and the Straits connecting it with the Atlantic Ocean.

THE additions to the Zoological Society's Gardens during the past week include two Vervet Monkeys (*Cercopithecus lalandii*, ♂ ♀) from South Africa, presented by Mr. J. W. Lincker; a Squirrel Monkey (*Chrysothrix sciurea*, ♀), a Yellowish Capuchin (*Cebus flavescens*, ♀) from South America, presented by Mr. H. C. Fernando Rohé; a Vervet Monkey (*Cercopithecus lalandii*, ♀) from South Africa, presented by Mr. Alfred Beit; two Common Peafowl (*Pavo cristatus*, ♂ ♂) from India, presented by Colonel Stucley; a Rocky Mountain Sheep (*Ovis montana*, ♀) from North America, a Suricate (*Suricata tetradactyla*) from South Africa, two White Ibises (*Eudocimus albus*) from South America, a Pennant's Parrakeet (*Platycercus pennanti*), a Rose Hill Parrakeet (*Platycercus eximius*) from Australia, deposited; two Red Kangaroos (*Macropus rufus*, ♀ ♀), two Peaceful Ground Doves (*Geopelia placida*) from Australia, purchased; a Thar (*Capra jemlaica*, ♀), a Great Kangaroo (*Macropus giganteus*, ♂), a Rufous Rat Kangaroo (*Œpyprymnus rufescens*, ♀), two Squirrel-like Phalangers (*Petaurus sciureus*), a Short-headed Phalanger (*Petaurus breviceps*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

ROYAL OBSERVATORY, CAPE OF GOOD HOPE.—Dr. Gill, in his report for the year 1896 to the Lords Commissioners of the Admiralty, sums up the work accomplished during the past twelve months. With regard to the McLean telescope, this is expected to be completely installed and in full working order before the end of the present year. During the last few years, Dr. Gill has somewhat necessarily restricted the amount of observational work in order to make more progress in the computation and publication of many arrears, and it is satisfactory, then, to hear that it has now become possible to again resume a programme of activity. Several important publications have been concluded in the last twelve months. Among them may be mentioned Vol. ii., containing a determination of the solar parallax and mass of the moon, from observations of Iris, Victoria, and Sappho, made in the years 1888 and 1889. Vol i. is also practically complete. The first volume of the Cape Photographic *Durchmusterung* is also ready for distribution, Vol. ii. being in course of printing. The observational work with the transit circle, equatorials, and astro-photographic telescope has been very considerable, and it may be mentioned that all the catalogue plates, with the last-mentioned instrument, have now been obtained. Out of the 230 chart plates, 169 have been satisfactorily exposed. The 7-inch equatorial has also been very busy in the hands of Mr. Innes, and, besides several new variables, 104 new double stars have been discovered. Dr. Gill refers also to the increase in staff and the necessity for a reversible transit circle for refined fundamental work, and mentions that these proposals have been favourably considered by the Lords Commissioners of the Admiralty and of Her Majesty's Treasury.

ZODIACAL RADIANTS OF FIREBALLS.—A remarkable feature about the appearance of slow-moving fireballs is that, as Mr. Denning has pointed out, they are directed from radiants in the western half of the sky and in the neighbourhood of the horizon. A further communication by him to the *Monthly Notices* for May, tells us that not only the most prominent, but the majority of the radiant points determined by observation are found to apparently congregate in a line approximately coinciding with the position of the ecliptic. Although there are a few exceptions to this law, Mr. Denning is nevertheless confident that there is sufficient weight of evidence which is of a suggestive and significant kind. In favour of this view, he gives a table of the observed facts which strikingly corroborate the idea advanced. He draws attention to the importance of accurately recording the directions of flight, and apparent paths among the stars of these bodies when they become visible, and of accumulating data which are necessary for trustworthy results to be based on them. All of us are aware of the great difficulty of accurately observing these strangers in our atmosphere, which come and go at generally most unexpected moments. They are, nevertheless, worthy of special study, and it would be very interesting if they were found to be revolving not only in direct orbits, but in orbits with small inclinations like the Jovian family of comets, as is suggested by Mr. Denning.

THE ROYAL SOCIETY CONVERSAZIONE.

THE second soirée this year took place on June 16. It was very numerously attended, and was more than usually brilliant, as, in accordance with a suggestion made by the President, the officers and many of the fellows appeared in academic or levée dress, to show respect to the Queen's guests who had been invited. The chief exhibits were as follows:—

Electrical effects of uranium: Lord Kelvin, G.C.V.O., F.R.S.

Experiments on kathode rays and some analogous rays: Prof. Silvanus P. Thompson, F.R.S.

Signalling by Hertz waves, as practised by Dr. Oliver Lodge, in 1894, with a Branly tube of filings as receiver, and now adapted to a Kelvin recorder: Dr. Alex. Muirhead.

(1) A selection of dried plants from Tibet, collected by Captain Deasy and Mr. Arnold Pike, Captain Wellby and Lieut. Malcolm; (2) views near the lake, and in the Queen's Cottage Grounds, Kew, by Monsieur and Madame de l'Aubinière: The Director, Royal Gardens, Kew.

(1) Experiments with Röntgen X-rays; (2) experiments with kathode rays; (3) Experiments with oscillatory electrical discharges: Mr. A. A. C. Swinton.

Experiments illustrating a new method of controlling the electric arc in its application to photo-micrography: Mr. T. A. B. Carver, and Mr. J. E. Barnard.

Living specimens of *Proteus anguinus*, Laurenti.—(1) Male and female; (2) pigmented individual from cave; (3) young specimen to show the eyes: Mr. E. J. Bles.

Pelagic animals from the west coast of Ireland: Mr. E. T. Browne.

Specimens of electric figures: Lord Armstrong, C.B., F.R.S.

Stress effects produced by convective electric discharges: Mr. J. W. Swan, F.R.S.

Crystals of diamond, separated from carburised iron: Prof. Roberts-Austen, C.B., F.R.S.

Commensalism amongst marine animals: The Marine Biological Association.

Microscopic image, formed exclusively by diffracted light: Dr. G. Johnstone Stoney, F.R.S.

Examples of animal-forms peculiar to Lake Tanganyika: Mr. J. E. S. Moore.

Microscopic sections of teeth of fossil reptiles: Prof. H. G. Seeley, F.R.S.

Illustrations of the absorption of Röntgen rays by certain elements and their compounds: Dr. J. H. Gladstone, F.R.S., and Mr. Walter Hibbert.

Ancient Egyptian knives and lance-head of flint: Sir John Evans, K.C.B., Treas. R.S.

Models of orchids, by Miss Emett, from plants grown in the Royal Gardens: The Director, Royal Gardens, Kew.

(1) New species of British Mymaridæ (egg parasites) or "Fairy Flies"; (2) aquatic and terrestrial specimens, living: Mr. F. Enock.

Medal struck in gold, silver, and bronze, to commemorate the sixtieth year of the reign of her Majesty the Queen: Mr. Horace Seymour, Deputy Master of the Mint.

Two induction coil contact makers and breakers: Sir David Salomons, Bart.

Demonstration of apparatus for exciting high vacuum tubes for X-ray work: Dr. John Macintyre.

There were the following demonstrations with experiments, and lantern illustrations:—

Signalling through space without wires: Mr. W. H. Preece, C.B., F.R.S.

Photographs illustrating the arrangements of the 1896 eclipse expeditions at Kiö and Novaya Zemlya: Mr. J. Norman Lockyer, C.B., F.R.S.

PROFESSOR MENDELÉEFF ON THE HEAT OF COMBUSTION.[1]

DULONG'S formula, which gives the heat of combustion of different solid and liquid fuels, as depending upon their composition, is, as is known, $\phi = 81\,c + 345\left(h - \frac{o}{8}\right)$, c, h and o representing the percentages of carbon, hydrogen, and oxygen in the fuel.

If a general expression, $\phi = \mathrm{A}c + \mathrm{B}h - \mathrm{C}o$, be taken, the numerical value of the coefficient $\mathrm{A} = 81$ must be maintained, because it corresponds to pure charcoal, and all known data (from 8140 to 8060) prove that the figure 81 must really be taken for each per cent. unit of carbon in the fuel (the accuracy of the measurements being within the limits of from 1 to 2 per cent. of the total heat of combustion). For hydrogen, however, the coefficient $\mathrm{B} = 345$ cannot be maintained, because it has been obtained out of data relative to the burning of gaseous hydrogen, while in usual solid or liquid fuel the elasticity of the gas is lost; its hydrogen must be considered as if it were liquefied, and consequently B must not be, according to what is known, more than 300 (admitting, as is usually done, that the water obtained during combustion is in a liquid state).[2]

In order to find the true coefficients suitable for practical purposes, Mendeléeff took the figure $\phi = 4190$, which is quite correct (within 1 per cent.) for pure cellulose, as also the average from 79 most complete measurements for fat coals (by Maler, Alexeyeff, Damski, Diakonoff, Miklaschewski, Schwanhöfer, and Bunge), and the average for naphtha fuel, and he has found:

$$\phi = 81\,c + 300\,h - 26\,(o - s),$$

which formula represents,[3] with an accuracy of from 1 to 2 per cent., the heat of combustion of pure charcoal, coke, coals, lignites, wood, cellulose, and naphtha fuels; of course, it applies to the best determinations only, especially to those which were made in a calorimetric bomb, where the error is less than 1 to 2 per cent.[4]

This formula is an approximate empirical expression of facts; but it corresponds at the same time to the numerical value of the coefficient B for hydrogen, which could be expected from theoretical considerations.[5]

THE SCIENTIFIC REQUIREMENTS OF COLOUR PHOTOGRAPHY.

ON Tuesday evening, June 1, in the Examination Schools, Oxford, Captain W. de W. Abney, C.B., F.R.S., gave the sixth Robert Boyle Lecture before the Oxford University Junior Scientific Club. The President, Mr. R. A. Buddicom, was in the chair, and about 800 members and their guests were present.

The subject chosen by Captain Abney was "The Scientific Requirements of Colour Photography." The following is an abstract of the lecture:—

Colour photography and photography in natural colours are two distinct methods of arriving at the same end, namely, the production of a picture of objects, coloured as they naturally appear to the eye. Both have been accomplished and depend on the application of science, but in the case of the former additional knowledge is requisite of the mode of action of the retina and of theories of colour vision.

In colour photography the theory of colour vision usually adopted is the Young-Helmholtz three-colour theory, in which red, green and blue are selected as primary colours, and not the red, yellow, blue of the artist. Captain Abney pointed out the difference between colour and colour sensation, and placed his colour sensation curves before the audience. These curves enable particular coloured screens to be selected, so that if transparencies from three photographs of the same object, taken one through an orange screen, one through a green, and one through a blue, be each illuminated by its own peculiar coloured light, and the three images be superimposed, the effect is to reproduce a picture of the object in its original colours. The colours of the screens used for taking the negatives must not be such as to allow only monochromatic light to pass. Thus the red screen must allow some orange, the green some yellow, and the blue some green, so that the lights through the three screens overlap somewhat.

The viewing screens, on the contrary, should be as nearly monochromatic as possible. By these means Mr. Ives has, in his chromoscope, been able to present to view photographs of natural objects in the colours in which they appear to the eye.

The next process described was that of Dr. Joly, of Dublin, who, basing his work on the same theory of colour vision as Mr. Ives, reproduces in colour by means of a single negative. This method is essentially founded on what may be called a happy imperfection of the eye. The human eye is incapable of separating points which lie very close to one another. In an engraving, the black lines, close together on a white surface, blend with the white surface to form shades of grey. Dr. Joly's method is to rule lines 1/200 inch broad on a transparent screen, touching one another and being coloured alternately red, green and blue. The lines are of such a depth of colour that the mixture, if made by rotating sectors, would appear white or grey. This screen is used for viewing. To make the negative another exactly similar screen is placed in front of the plate, but the colours of the lines on this differ, just as Mr. Ives' coloured screens for taking the negatives differ from his viewing screens.

When the negative is taken, a transparency is made from it, and the viewing screen is placed behind it, so that the red line covers the place through which the orange negative was taken, and so on. Then, and not till then, the picture appears in its natural colours.

Instead of using transparencies and coloured films, transparent inks may be used to produce pictures by three printings.

The next process described was the oldest, namely, the production of colour by the action of light itself. The present year is its jubilee. Becquerel found that if, instead of iodising a plate, he chlorinised it, and then exposed it to white light, it gradually assumed a violet tint, and if, in this state, he exposed it to the spectrum he was able to obtain the colours of the spectrum on it.

Abney, some years ago, showed that the red tint was due to the lavender-coloured material taking up oxygen, whilst at the violet end the subchloride became further reduced: thus the big molecules formed by the addition of the oxygen vibrated slower, whilst the abstraction of chlorine gave smaller ones vibrating quicker. Since he was able to get the same effect on collodion plates, it is not probable that the colours are due to stationary waves, because, if so, they could only be viewed by reflected light. Unfortunately, however, these colours, from the very manner in which they were produced, were not permanent, and no method has been devised for fixing them.

The last method Captain Abney described of obtaining photographs which showed colour, but not coloured photographs, was that of Lippmann, who found that if, by means of reflection, he obtained stationary waves in the film, on development the silver was deposited between the nodes. On reflecting light from such a "noded" plate, the proper light alone was reflected, and the photograph, viewed at a particular angle, appeared in its natural colours. If looked at by transmitted light, these photographs have merely the appearance of ordinary negatives.

The proceedings closed with a vote of thanks to the lecturer, proposed by Prof. Burdon Sanderson, and seconded by Mr. A. F. Walden.

THE INTERNATIONAL CONGRESS ON TECHNICAL EDUCATION.

THE International Congress on Technical Education, opened by the Duke of Devonshire at the Society of Arts on Tuesday, June 15, was continued on the three following days. Many important papers were read, and there was a large attendance of delegates from the continent and abroad. We have extracted from the *Times* the subjoined brief reports of a few of the papers read and the discussions which took place upon them.

[1] Translated from the *Journal* of the Russian Chemical and Physical Society, vol. xxix. fasc. 2, 1897, pp. 144. (Minutes of meeting of February 18, 1897.)

[2] Maler has also adopted that coefficient, taking $\mathrm{C} = 30$.

[3] The percentage of sulphur was not determined in each measurement, and consequently the coefficient $+26$ is determined only approximately.

[4] If the water which is formed during combustion is represented, as it is in reality, in the shape of steam, then 600 aq must evidently be deducted from ϕ; aq representing the weight of water obtained from the combustion of one unit of fuel.

[5] In those cases where different values of ϕ were received for the same composition of coal, the discrepancies could be explained by errors of measurements; there was no foundation to suspect isomerism. A good deal of the now prevailing incertitude is also due to the incomplete data relative to the amount of combustible sulphur.

Several papers on the aims of instruction in chemistry were read on the opening day. In one paper Dr. Otto N. Witt, Professor of Chemical Technology at the Polytechnic School of Berlin, said he could not admit any fundamental difference in the methods of research of pure and applied chemistry, consequently he could not admit the necessity for a difference of instruction for the two. A well-organised instruction in pure chemical science would, in his opinion, be the best preparation of any young chemist for his future career. He held that schools for producing specialists were not wanted; for specialism came as a matter of course in later life. Chemists were needed who embraced their science as a whole, and who were incapable either of separating practice from theory or theory from practice.

Dr. H. E. Armstrong urged the need of better organisation in regard to instruction dealing with the preparation of the soil for agricultural purposes.

Dr. Gladstone, in the course of a paper on "The Teaching of Chemistry in Evening Continuation Schools," said that when the evening school was situated in the neighbourhood of factories it would be allowable and even desirable that the illustrations should be chosen with some reference to the prevailing industry.

Sir H. Roscoe, in opening a general discussion on the subjects dealt with in the foregoing papers, pointed out that what we in England suffered from was the failure of our manufacturers to see, as they ought to see, the importance of the highest scientific training for their *employés*. Recently he visited some large colour works near Frankfurt, where 100 men were employed, including many highly-trained scientific chemists who had devoted years to original research with a view to making new discoveries. One *employé*, who received 1000*l*. a year, worked for several years without producing any results. But eventually he made a discovery which repaid the firm ten times over and placed an entirely new branch of manufacture in their hands. Scientific teaching had taken up a sound position already, and if manufacturers would only appreciate its value we could turn out scientific men as well as any country in the world.

This view was given support by a paper on "The Teaching of Chemistry," by Prof. G. Lunge, of Zurich, read by Sir H. Trueman Wood. The writer held that, to raise English chemical industry to the foremost rank (which was disputed to it at present in several important branches), it was necessary that the technical management of chemical factories should not be left in the hands of "rule-of-thumb" men, but should be intrusted to real chemists. These men should have a much fuller education than the majority of chemists seem to obtain at present in Great Britain, which meant that they must spend more time and money on their training than they generally did. At college the student should receive a thorough training in scientific chemistry, taking this in its widest meaning, not merely as a "testing" exercise. Next to this, but not to the same extent, he should be taught physics, mineralogy, technology, mechanics, and the elements of engineering. As to whether foremen or even the common workmen should possess a certain knowledge of chemistry and technology, such as may be imparted at Board schools or at night classes for adults, Prof. Lunge was afraid that such knowledge was quite useless to ordinary workmen, who had simply to do as they were told, and who might do more harm than good by trying to apply a superficial idea of the nature of the operations which they had to perform, without possibly having a real insight into them. He did not even think that, apart from isolated exceptions, such knowledge was much good to the foremen, whose duty it was to carry out their instructions and to see that the men did their work as prescribed by the staff, but who were not to meddle with the chemical process itself.

Prof. Silvanus P. Thompson, in discussing the paper, said there should be a distinction between the different branches of the subject. He urged that where a great industry was localised science should be applied to that industry, and an institute should be put there devoted to monotechnical rather than polytechnical instruction. Training in research was absolutely necessary, and specific research should not be undertaken too soon by students who had not been taken through an all-round course in chemistry.

Mr. G. R. Redgrave, Chief Senior Inspector Science and Art Department, read a paper giving an historical retrospect of "The Intervention of State in Secondary Technical Education," in the course of which he urged that something of the nature of the German Realschule, but with a far larger proportion of practical science work and manual training, should be our model for the secondary school in this country.

On Wednesday, June 16, Sir Philip Magnus, in a paper on "Theory and Practice in Trade Teaching," referred to the difficulty of determining the true relation of theory and practice in teaching the technology of any trade, and in the Technical Instruction Act, which expressly forbade the teaching of the practice of a trade in any technical school. But in the great majority of industries the practice of the trade was best acquired in the factory and shop, and the instruction of the technical school should be supplementary only to the experience obtained in commercial work. By this principle nearly all our technical classes were regulated. Although a technical school might be equipped almost as completely as a trade shop the equipment served a very different purpose. Its object is the production of intelligent workpeople, and not the production of saleable commodities. The practice a student obtains in a technical school was intended to enable him to understand appliances of his trade, and to use them with care and judgment.

Mr. S. H. Wells, Principal of the Battersea Polytechnic, pointed out that the greatest of all difficulties in connection with technical classes was undoubtedly the provision of satisfactory and efficient teachers. The first and most natural qualification of a teacher of technical classes was that he should possess a practical knowledge—acquired in the factory or workshop—of the subject to be taught; the second, that he should possess a sound knowledge of the arts and sciences applicable to the subject; and the third, that he should be able to impart his knowledge to others, to arrange a syllabus of instruction, to manage a class, in a word, to teach.

Prof. Ayrton gave an account of the Central Technical College, South Kensington. He remarked that the facilities for technical instruction in London were increasing every day, but a system of coordination was greatly needed.

Prof. Silvanus Thompson urged the coordination of educational institutions from the highest to the lowest. Dr. Garnett said that if artisans were to be attracted to technical classes the teachers must be acquainted with the practical details of the trades to which the artisans belonged. It was difficult to find theoretical and practical knowledge combined in one man. The presence of practical workmen he had found a great advantage when holding his classes. Prof. Viriamu Jones (Cardiff) believed that artisans would ultimately avail themselves of the best instruction to be obtained in each science bearing on their trade. They would feel that teaching by specialists was better for them than teaching from those who might have learnt but little of the subjects. Mr. Reynolds (Manchester) pointed out the wasteful overlapping that prevailed in connection with technical instruction. The Technical Instruction Act, which forbade the practice of a trade being taught in technical schools, was practically a dead letter in Lancashire, and deserved to be. Prof. Chatterton (Madras) said that the great difficulty in connection with the technical schools in the Madras Presidency was to obtain efficient teachers. Mr. Mundella, M.P., said that proper elementary education was indispensable before working men could derive benefit from special technical instruction. Parliament must raise the limit of age for compulsory attendance at elementary schools to that which prevailed in other countries. If his students had not been well educated in elementary subjects the science master was called upon to make bricks without straw.

The Chairman, Major-General Sir J. Donnelly, in concluding the discussion, referring to the interpretation of the Technical Instruction Act, said technical instructors might teach how a thing was done, but not carry their training so far as to give the rapidity and dexterity of manipulative skill required for the craftsman or journeyman. Looked at in that way, there was no difficulty in working the Act.

Mr. Mundella, M.P., in introducing Prof. T. V. Diefenbach, to read a paper on "Technical Education in Würtemberg," referred to the marvellous progress made by the kingdom of Würtemberg during the last forty years. A commission from England, which visited Würtemberg to inquire into their system of technical education, reported that they had seen no part of Europe more progressive than Würtemberg, and they were assured that there was not a single pauper in the whole country. He wished he could say the same of England.

Sir Joshua Fitch then read a paper on "Some Limitations to Technical Instruction," in which he entirely admitted that our

school instruction had long been too bookish, too little practical, and that the friends of technical instruction were fully justified in calling attention to the grave deficiencies in our system, especially to the want of sounder teaching in physical science and of better training in the application of those sciences to the enrichment of the community and to the practical business of life.

Prof. Oscar Pyferven, of the University of Ghent, who represented the Belgian Government, read a paper on "L'Enseignement Professionnel et l'Initiative Privée en Belgique"; and M. E. Sève (Consul-General for Belgium) read a paper on "Technical and Commercial Instruction in Belgium."

Prof. Wertheimer, principal of Merchant Venturers' Technical College, Bristol, read a paper on the influence of various examining bodies on the progress of technical and commercial education in England. He held that it behoved them to watch closely any attempt to establish new examinations. The technical instruction committees of some County Councils were already instituting examinations of their own; in a very few cases these might be necessary to meet special local requirements. But, as a rule, they were not needed, and it would be wiser to endeavour to modify existing examinations, if necessary, rather than to establish new ones.

On Thursday a paper by Mr. Quintin Hogg, on "Polytechnics," was read by Dr. William Garnett, who also gave an account of the work of the Technical Education Board of the London County Council. In commenting upon the latter paper, Sir John Lubbock said that too much of the money went to the elementary and too little to the higher training of those who were to be the leaders of industry.

The next paper was on "Reforms in the Organisation of Technical Education," by Prof. Silvanus P. Thompson, F.R.S., who said that the provision made on the continent for the higher training in chemistry might be understood from the fact that the entire establishment of the Regent Street Polytechnic, chemical laboratory, gymnasium, swimming bath, theatre, kinematograph, and all, might be accommodated within the space provided for the chemical laboratory alone in the polytechnic at Munich. The chemical laboratory of the polytechnic at Zurich exceeded in contents the whole of the technical schools at the People's Palace. The chemical laboratory of Berlin was larger than the whole building of the City of London College. The physics laboratory at Zurich was considerably larger than the whole building of the Finsbury Technical College, and the cost nearly twice as much.

The remainder of the papers on Thursday dealt with commercial education, the organisation of examinations, and the development of technical instruction in secondary schools.

The concluding session of the conference, held on Friday last, was devoted exclusively to the consideration of papers by ladies on a variety of aspects of technical and secondary education. Mr. Mundella, M.P., presided.

Miss Alice Mitchell read a paper on the "Teaching of Domestic Economy in Girls' Secondary Schools." In the high schools she thought the great failure was the absence of the practical side, for all schools suffered from the want of laboratory facilities.

A paper was read by the Countess of Warwick on "Technical Education in Rural Districts." She said she had undertaken the task believing that a careful development of the subject might help not a little to stay the depopulation of our villages. An intelligent appreciation of natural phenomena and natural laws, when applied to agriculture, might go a long way to relieve the depression from which country districts were so keenly suffering. The elements of chemistry and physics, geology, botany, and zoology might be taught with great advantage to the future farmer or practical agriculturist. We should no doubt some day have a rational system of education, and not a disjointed one, as at present, when due regard would be paid to the co-ordination of subjects of instruction. At present, the great want was co-operation in all branches, but this was likely to remain while every branch of education was under a separate and distinct authority, often antagonistic to each other and encroaching on one another's grounds. In the same town they might see the voluntary schools, board schools, middle schools, grammar schools, and technical classes all being carried on under separate rate authorities, who have no regard for each other's work, and consequently overlapping each other's efforts, in many directions leading to waste of time, money, and energy. District technical schools should be opened within given areas, or a technical side to existing schools be developed; or, perhaps better still, the schools of the whole district should be affiliated, with a technical school attached, for the use of the pupils from all. The money received by county councils for the technical education grant might be well spent in equipping such schools. If a plot of land could be attached to the technical schools, it would be very useful for the purpose of experiment and demonstration in the field.

At the close of a discussion, the Chairman said Lady Warwick's paper was so full of suggestions that it was impossible to comment upon them briefly. It involved educational reforms of the highest importance, and the first was that one public authority in each district should see that education was properly carried out. Lady Warwick had put aside the utilitarian view; nevertheless, this was a subject of considerable moment, both in town and country. Denmark was far ahead of us in agricultural matters, and sent to this country produce to the value of 10,000,000*l.* annually. It was an extraordinary thing that we should have to pay enormous sums of money to foreign countries for supplies which we ought to be able to provide much better at home. They were told that foreigners were more intelligent than our people; and although he did not believe that, we should educate our people and try to make them as intelligent, fruitful, and productive as their foreign competitors.

A large number of other papers were read before the Congress, but the limitations of space prevent us from referring to them.

SCIENTIFIC SERIALS.

American Journal of Science, June.—Bacteria and the decomposition of rocks, by J. C. Branner. In criticism of the somewhat largely prevailing idea that bacteria are the cause of much of what is called the decay of rocks, it must be remembered that nitrifying bacteria not only do not penetrate the rocks themselves to any considerable depth, but they do not even penetrate the soil to a depth of more than three or four feet. Granites are, on the other hand, often decomposed to depths of more than 100 feet.—On Wellsite, a new mineral, by J. H. Pratt and H. W. Foote. This mineral occurs at the Buck Creek corundum mine in Clay Co., North Carolina, associated with albite, felspar, and hornblende. No crystals found exceed 2 mm. in length. They are monoclinic and twinned, brittle, with a vitreous lustre and no apparent cleavage. They are colourless and transparent or white, with a hardness of between 4 and 4·5, and a density of about 2·3. Chemically, it is a barium or calcium hydrated silicate corresponding to the formula $RAH_2Si_3O_{10}.3H_2O$, and is therefore allied to Phillipsite, harmotome, and stilbite.—The magnetic increment of rigidity in strong fields, by H. D. Day. The author employs extremely strong fields in order to bring out clearly the relation between magnetisation and the phenomena of magnetic rigidity. He shows that long after magnetic saturation has been reached the increase of rigidity due to increase of field intensity goes on, and that the limit of the latter is not reached even with the highest field intensities attainable. As the field becomes stronger, the increment of rigidity varies more and more regularly with the twist, the tendency being that in fields indefinitely large the increment of rigidity would be proportional to the twist applied.—The broadening of the sodium lines by intense magnetic fields, by A. St. C. Dunstan, M. E. Rice, and C. A. Kraus. The phenomenon of the magnetic broadening of the sodium lines discovered by Zeemann may be easily observed with the aid of Michelson's interferometer. Light from a Bunsen flame containing a sodium salt is sent on to a plate of plane glass which partly reflects and partly transmits it to a fixed and a movable mirror. The fringes produced in the telescope by their recombination are made less visible by the broadening of the line observed. The curve of visibility gives the amount of the broadening. In the most intense field the broadening is in the ratio of 1 to 1·7. It is proportional to the field intensity.—The relative motion of the earth and the ether, by A. A. Michelson. This was investigated by an interference experiment in which a beam of light was made to travel round a rectangle in a vertical E. and W. plane, and to return along the same path. If the ether near the earth's surface moves with the earth, and the ether above the atmosphere is stationary, there must be some difference of

velocity in the upper and lower paths, which would be indicated by a displacement of the fringes. No such displacement is observed, and hence we must conclude that either the ether is absolutely at rest everywhere, or that the earth drags it with it up to many thousand miles from the surface, or, lastly, that the length of all bodies is altered by their motion through the ether.

Bulletin of the American Mathematical Society, May.—Systems of continuous and discontinuous simple groups, by Dr. L. E. Dickson (read at the April meeting of the Society). This paper is in continuation of some results announced at the Buffalo meeting (August 31, 1896), and consists of four sections. § 1 enumerates the known systems of discontinuous simple groups; § 2 the systems of finite continuous transformation groups which are simple; § 3 gives an elementary deduction of certain groups in § 2, viz. the groups in the $l(2l+1)$ parameters, isomorphic with the general projective group of a linear complex in R_{2l-1}, and a proof of their simplicity; § 4 discusses the semi-simple linear homogeneous groups whose defining function is the sum of n determinants of order $q>2$. The contents of §§ 3, 4 were presented by Prof. Lie (February 19) to his class, and he stated that "the interesting result of § 4 was new, and not what one would have expected."—On the number of roots of the hypergeometric series between zero and one by Mr. M. B. Porter (read at the March meeting). Klein's solution was published in 1890 (*Math. Ann.*, vol. xxxvii.). Solutions by Hurwitz and Gegenbauer are given in the *Math. Ann.* (vol. xxxviii.) and the *Wiener Sitzungsberichte* (vol. c.^{2a}) respectively. The object of the present paper is to apply two theorems of Sturm (*Liouville's Journal*, vol. i.) to the solution of the problem.—Another paper, read at the March meeting, is by Prof. J. Pierpont on modular functions. This treats the subject from the point of view of H. Weber's Memoir, zur theorie der Elliptischen Functionen (*Acta Math.*, vol. vi. p. 329; *cf.* also his Elliptische Functionen und Algebraische Zahlen, 1891).—In the Notes are given the mathematical courses for the summer session at the Universities of Chicago, Leipzig, and Munich.

Bulletin de la Société des Naturalistes de Moscou, 1896, No. 1.—Contributions to the knowledge of the Urticaceæ and the Moraceæ, by M. Golenkin, with one plate. The inflorescence and the disposition of leaves are treated in this second instalment (in German).—A preliminary catalogue of the Lepidoptera of the province of Kazan, by L. Krulikovski, continued (in Russian).—Study of the embryonal development of *Gammarus pulex*, by Marie Rossyskaia-Kojevnikova, with one plate (in French).—Materials for the mycological fauna of the province of Smolensk, by A. Jaczewski (in French). The author has found in that province 550 species of fungi, out of which 408 are new for that region, and he gives the list of these species.—On the structure, function and evolution of the Nematocysts of Cœlenterata, by N. Iwanzoff, with four plates (in German). An elaborate work, made at the zoological laboratories of Naples and Villefranche, to be continued.—On the rotation of the earth, supposed to be fluid in its interior, by Prof. Th. Sloudsky, being a purely mathematical inquiry, continued from a previous number.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 13.—"A Dynamical Theory of the Electric and Luminiferous Medium. Part III. Relations with Material Media." By Joseph Larmor, F.R.S., Fellow of St. John's College, Cambridge. Received April 21.

This series of papers is mainly concerned with the development of electrical and optical theory on the basis that electricity is constituted of discrete atomic charges or electrons. It has been shown in the previous papers that the facts of electrodynamics require this hypothesis and are consistent with it. The hypothesis was arrived at from the point of view of the properties of the æther, the conception of the electron as a permanent strain-centre being a necessary feature of a theory of an elastic æther. This idea is here developed and illustrated by aid of a specification, on Lord Kelvin's lines, of a gyrostatic material structure which would possess the rotational elasticity characteristic of the æther, and at the same time contain such strain-centres. The conception of a medium of elastic solid type containing mobile discrete strain-centres is also touched upon, by way of illustration and contrast.

In the previous papers the relations of electromotive and optical phenomena in matter at rest had been developed on this basis. When the matter is considered as in motion through the æther, or when electric forces on matter are treated, we obtain a definite and sufficient basis of connection between matter and æther by assuming that the electrons are attached to the atoms of matter. On this basis the electric and optical relations of moving material media are here developed at length. The more speculative question, as to how far a constitution of the material atom which makes it consist wholly of a system of electrons describing orbits round each other suffices to represent or illustrate the properties of matter, comes under consideration in various respects: this hypothesis in many of its features would agree with the well-known theory of vortex atoms.

The theory of refraction equivalents is developed, leading to Lorentz's results. The theory of optical dispersion is treated from the generalised standpoint that the molecule vibrates about a configuration of steady motion instead of one of rest: it appears, also, that the formula usually given for the square of the refractive index must be replaced by a similar formula for the Lorentz refraction equivalent.

The character of the mechanical forces that are developed in fluid and solid material media by the electric attractions between the polarised molecules of which they are composed, is considered, and expressions are obtained for them. A distinction is here essential between those forces between neighbouring molecules which are compensated locally, and the ones which give rise to transmitted mechanical force which must be compensated by regular mechanical stress in the medium; somewhat in the manner of the corresponding distinction employed by Young and Poisson in the theory of capillarity. It leads, through the negation of the perpetual motion, to the specification of a function which is the *mechanical* or *organised* energy of the material medium: this is different from the *available* or *free* energy of thermodynamics, which is also represented by an analytical function on account of the negation of the unlimited availability of diffuse thermal energy: it is, of course, also different from the *total* or *aggregate* energy of the molecules of the medium, about which little can be known in detail. The theory of osmotic forces is formulated in relation to the available energy with which they are connected, as they are related to the individual molecules sifted by porous partitions and not to the element of matter in bulk: the known general laws of chemical equilibrium are formulated as corollaries to the same principle. On the other hand, the mechanical forces in a fluid molecular medium polarised in any manner are expressed in terms of the distribution of *mechanical* energy of polarisation. The doctrine of *energetics* (including the conception of temperature), which forms a sufficient basis for the descriptive explanation of the mechanics of statical or steady material systems, thus reposes on the negation of the two types of perpetual motion above mentioned, and therefore ultimately on the discrete constitution of matter.

A thermodynamic application which possesses interest, both from the light it throws on the nature of magnetism and from the circumstances that in it the heat supply is calculated indirectly from the magnetic energy that runs down, is the relation between magnetic susceptibility and temperature in substances not in the very susceptible or ferromagnetic condition. According to the Weberian theory, which fits in with the present view, diamagnetic energy which is not compensated mechanically goes to the induction of Amperean currents in the molecules; while paramagnetic energy not thus compensated goes to orientating the molecules, and thus into heat. It follows that the diamagnetic coefficient is independent of temperature: on the other hand, it is shown that the paramagnetic coefficient should vary inversely as the absolute temperature. These laws were discovered experimentally by Curie, who finds from a very extensive investigation that they have the same order of accuracy at sufficiently high temperatures as the ordinary gaseous laws: at lower temperatures and in ferromagnetic substances the control of the polarised molecules arises in appreciable part from the magnetic interaction of their neighbours, thus vitiating the law as well as introducing effects of hysteresis. The well-known model of Ewing would thus represent an ideal perfect ferromagnetic in which the control arises wholly from the latter cause.

In application of the previous results as to how far physical actions can be considered as transmitted across the æther by elastic stress, the conditions are formulated under which the

correlative principle utilised by Poynting is valid, that the actual rate of change with time of the organised or mechanical energy within any region is expressible explicitly as a surface-integral over its boundary.

The mechanical effects of light-waves are reconsidered in the light of this molecular theory. The conclusion is reached that such effects are wholly associated with absorption of the radiation, that no influence of perfectly transparent media on radiation can provoke a mechanical reaction. There is a mechanical force acting on an absorbing mass, in the direction of the incident radiation and equal to $E(1 - m^{-2})$, where E is the energy absorbed per unit time and m is the real part of the index of refraction. Partial analogies are furnished by the mechanical effects of Hertzian radiation on a medium built up of conducting linear circuits, and of sound waves on a medium formed of a system of resonators.

As an application of the law of the mechanical forcive on dielectrics, the changes of dimensions of a condenser under electrification are considered. The problem is found to admit of exact solution if the condenser layer consists of a closed sheet, of any form, but of uniform thickness. In that case the mechanical stress in the material of the sheet proves to be simply of the type of the Faraday-Maxwell stress. The theory is compared with Quincke's experimental results: their main features are verified, including those which led Quincke to assign a wholly non-mechanical origin to the effect: but something less than half the change of volume remains over as an intrinsic electric deformation, not due to the transmitted mechanical forces.

Finally a series of practical illustrations of the mechanical theory are treated, some of which have already been employed for experimental measurement, and which are capable of still further application. The mechanical circumstances attending the refraction of uniform fields of electric force by fluid media are developed. The theory of various arrangements for measuring electric tractions and pressures in fluid dielectrics is worked out. The effect of an electric field on the velocity of ripples on the surface of a conducting or a dielectric fluid is determined: as also are the relations of electric polarisation to vapour tension and fluid equilibrium. The internal mechanical forces in a complete magnetic circuit are examined, and also the traction between the interfaces when it is divided: and the mode of calculation of the stress in a sphere of iron in a uniform magnetic field is indicated, agreeing for this case with Kirchhoff. The mutual influence of stress and magnetisation is analysed, with reference to the experimental investigations of Bidwell.

June 3.—"Mathematical Contributions to the Theory of Evolution. On the Relative Variation and Correlation in Civilised and Uncivilised Races." By Miss Alice Lee, Bedford College, and Karl Pearson, University College. Received April 9.

The numerical constants of this paper were calculated in the hope of reaching some general ideas on comparative variation and comparative correlation in the case of civilised and uncivilised races, and further of determining, if possible, any general law connecting relative sexual variation and relative sexual correlation with the degree of civilisation, and so, with what is probably inversely proportional to the degree of civilisation, namely, the intensity of natural selection.

The following two principles seem to flow from a study of variation in the organs of man:—[1]

(*a*) Civilised man is more variable than uncivilised man.

(*b*) There is a greater equality of variation for the two sexes in uncivilised than in civilised races. Civilised woman appears, on the whole, to be slightly more variable than civilised man.

Both these principles are in accordance with the intensity of the struggle for existence—and the amount, consequently, of natural selection—being greater for uncivilised than for civilised races, and, further, greater for men than for women in the latter races.

The problem of correlation is, however, of a less simple character. While the action of selection can be shown theoretically to reduce variation, it by no means follows that it reduces correlation. Indeed, selection may increase, decrease, or reverse correlation at the very same time as it is reducing variation. We have then the following problems to guide us in the treatment of actual statistics:—

[1] See "Variation in Man and Woman," by K. Pearson: "The Chances of Death," vol. i. pp. 256–377, where some 155 cases of human variation for both sexes are dealt with.

(*a*) Is correlation more intense among civilised than among uncivilised races?

(*b*) How does the relative correlation of the sexes differ in civilised and uncivilised races?

(*c*) Is there any marked prepotency of either sex in the matter of correlation?

These are the problems which the present calculations were designed, not to definitely solve, but to illustrate.

Unfortunately, adequate measurements on living members of uncivilised races are not very numerous, nor for the purposes of correlation generally very satisfactory. Reasons are given in the paper why long bones form more suitable material than skulls, and the measurements made in France by Rollet, and on the Ainos in Japan by Koganei, are discussed at length.

The following results are suggested by a discussion of the measurements.

(1) Civilised man has progressed as a rule on primitive man in size, variation, and correlation.

(2) This progression can hardly be accounted for by increased selection (because of the increased variation), not by decreased selection (because it is inconsistent with the relative changes in male and female size). It might possibly be accounted for by decreased selection and improved physical conditions.

(3) Woman is more variable than man in civilised races.

(4) Woman is more highly correlated than man in civilised races.

(5) In uncivilised races the sexes are more nearly equal in the matter of size, variation, and correlation than in the case of civilised races.

(6) It is impossible to say that civilised woman is nearer to the primitive type than civilised man. While civilised man differs more from the primitive type than civilised woman, so far, probably, as absolute size is concerned, he has made only about half her progress in variation, and hardly any progress at all in correlation.

(7) The causes (*e g.*, lessening of selection) which tend to increase variation may also increase correlation. In other words, the intensity of the struggle for existence is not necessarily a measure of the intensity of correlation.

Mathematical Society, June 10.—Prof. Elliott, F.R.S., President, in the chair, and subsequently Major MacMahon, R.A., F.R.S., Vice-President.—Mr. W. W. Taylor gave, in some detail, a description of several models of the regular convex and star solids.—The following papers were communicated:—The calculus of equivalent statements (sixth paper), by H. MacColl; on the primitive substitution groups of degree fifteen, by Dr. G. A Miller; and a generalised form of the binomial theorem, by Rev. F. H. Jackson.

EDINBURGH.

Royal Society, June 7.—Prof. Geikie, F.R.S., in the chair. —Sir William Turner read a paper by Dr. Broom, South Africa, on the comparative anatomy of the mammalian organ of Jacobson.—Prof. C. G. Knott gave the concluding paper of the series on magnetic strains, for which the Council has awarded him the Keith Prize for 1893–95. His results may be summarised thus:—All the iron and steel tubes follow approximately the same law as regards their longitudinal dilatation in a longitudinal magnetic field. In moderate fields the dilatation is positive; but it is negative in higher fields. The maximum occurs in field 150 ± 50, according to the thickness of the walls —the thinner the wall, the lower the field corresponding to the maximum dilatation. The great diversity in the volume-changes within the cores shows that the transverse dilatations must be of such a value as to be in some cases less than half the longitudinal dilatation, sometimes greater. This is particularly true of the steel tubes. The behaviour of nickel is much simpler than that of iron. On the whole, the cubical dilatation is determined by the longitudinal dilatation, both being negative and more nearly alike in order of magnitude than in the case of iron. Excepting for the tubes of narrowest bore, the transverse dilatation is positive, and about ¼th or ⅓th of the longitudinal dilatation. The change of volume of a mass of nickel turnings enclosed in a brass tube and placed in the magnetic field is much smaller than the volume-changes in the bores of the tubes. The cubical dilatation is always positive, and increases steadily from $1 \cdot 56 \times 10^{-8}$ in field 107, to $27 \cdot 4 \times 10^{-8}$ in field 570.—In a paper on the solution of equations connecting linear vector functions, Prof. Tait derived a general proposition regarding the commutativeness of strains, and noted connected questions.

—On the electrification of air by uranium and its compounds, by Dr. J. C. Beattie. Experiments were described to test the electric state of the air in the neighbourhood of metallic uranium, or of other metals on which a salt of uranium had been deposited, when these were charged to a positive or negative potential. The method adopted was the electric filter method of Kelvin, Maclean, Galt. It was found that the air drawn away from the negative electrode of a Ruhmkorff inductorium, or from the kathode of a Crookes' tube, or from the wire joining the negative electrode of the coil to the kathode of the tube, was always negatively electrified. On the other hand, the air drawn from the neighbourhood of the positive electrode of the coil, or from the anode of a Crookes' tube, or from the wire joining them, was found to be positively electrified. This positive electrification of the air was always less than the negative corresponding. With uranium insulated in a metal cylinder and connected to the terminal of a battery, while the cylinder and the other terminal were connected to the case of a quadrant electrometer, the air was electrified positively when the uranium was electrified positively, and negatively when the uranium was electrified negatively. With the metal cylinder insulated and joined to one terminal of the battery, while the uranium still inside the cylinder and the other battery terminal were connected to the electrometer case, it was found that the air was negatively electrified when the cylinder was positively electrified, and *vice versâ*. The negative electrification of the air was always less than the corresponding positive electrification. Both attained a maximum value when the difference of potential was between 10 and 20 volts per cm. of air space. The same results were obtained when metals were covered with salts of uranium and then charged to positive and negative potentials. Dr. Beattie also read a note on this subject by Lord Kelvin. The following is an abstract of the note:—The effective conductivity induced in the air by the uranium influence is, of course, greatest in the immediate neighbourhood of the uranium, but there is something of it throughout the enclosure. Hence it may be expected that electricity of the same kind as that of the uranium will be deposited in the air close around it, and electricity of the opposite kind in the air near the enclosing metal surface. And the quantity flowing from either the uranium or from the surrounding metal per sq. cm. of its surface increases but little with increased voltage when this exceeds 5 or 10 volts per sq. cm. Hence, if the dimensions and shapes of the uranium and of the surrounding metallic surface are such, that for small voltage, such as 10 or 20 volts, the electricity lodged in the air by discharge from the uranium preponderates over that discharged from the surrounding metal, the excess must come to a maximum and diminish, may be even down to zero, with greater and greater differences of potential; and at potential differences still greater the electricity lodged in the air from the outer metal may preponderate, and the electricity in the air drawn off and given to the filter be of opposite sign to that of the uranium which was found with the lower voltages. *Provided the configurations are such, and the voltages are so moderate that disruptive discharge does not intervene to any practically disturbing extent.*—On simple formulæ giving approximate values of the roots of the Bessel function of order n and its first derived function, in terms of the roots of (say) $J_2(x) = 0$, $J_3'(x) = 0$, (n even), or those of $J_3(x) = 0$, $J_4'(x) = 0$, (n odd), by Dr. W. Peddie. In this paper were given simple expressions by means of which the roots of $J_n(x) = 0$, $J'_{(n+1)}(x) = 0$ can be obtained when the roots of $J_\rho(x) = 0$, $J'_{(\rho+1)}(x) = 0$ are known ($\rho < n$). These expressions lend themselves readily to numerical calculation, and give values of the roots which become more and more nearly true as x increases. Even for the smaller roots, beyond the first two, the values found are highly approximate when $n - \rho$ is not too great.

Mathematical Society, June 11.—Mr. J. B. Clark, Vice-President, in the chair.—The following papers were read:—On superposition by the aid of dissection (continued), by Mr. R. F. Muirhead; on a method of studying displacement, by Mr. R. F. Muirhead; the isogonic centres of a triangle, by Dr. J. S. Mackay.

DUBLIN.

Royal Dublin Society, March 24.—Prof. E. Percival Wright in the chair.—A paper was presented by Mr. J. E. Duerden, of Kingston, Jamaica, on Jamaican Actiniaria (Part i. Zoantheæ), being communicated through Prof. A. C. Haddon. —Prof. W. J. Sollas, F.R.S., read a paper on an apparatus for submarine observation. Samples of new colours with metallic lustre, mosaics and pavement, lent by the Vitreous Mosaic Co., together with a collection of chemicals made by Harrington Bros. for the glass, china, and enamel industries, and for photography and electro-plating, were described by Prof. W. Noel Hartley, F.R.S.—Prof. E. J. McWeeney gave a demonstration of the bacillus of the bubonic plague.

April 21.—Prof. W. J. Sollas, F.R.S., in the chair.—On the possibility of boring and raising a portion of a coral reef from a great depth, and on an apparatus for demonstrating the folding of rocks due to lateral pressure, by Dr. J. Joly, F.R.S.—The formation of humus, its action in the nitrification of ammonium compounds, by Mr. W. E. Adeney.

May 19.—Prof. W. J. Sollas, F.R.S., in the chair.—Dr. J. Joly, F.R.S., read a paper on the volume change of rocks attending fusion.—Sir Howard Grubb, F.R.S., read some notes on a recent paper by Prof. Hale, of Chicago, respecting the relative merits of reflecting and refracting telescopes, (*a*) when used for visual work, (*b*) when used for photographic work.—Prof. D. J. Cunningham, F.R.S., made some observations on the Cape hunting dogs in the gardens of the Royal Zoological Society, Dublin.

PARIS.

Academy of Sciences, June 14.—M. A. Chatin in the chair.—Experimental verification of the theory of gradually varied flow in open channels, by M. J. Boussinesq.—Fossil forest of *Calamites Suckowii*. Specific identity of *Calamites Suckowii* (Br.), *Cistii* (Br.), *Schatzlarensis* (St.), *foliosus* (Gr.), *Calamocladus parallelinervis* (Gr.), and *Calamostachys vulgaris* (Gr.), by M. Grand 'Eury. In a fossil forest at Treuil, the remains consist almost entirely of *Cal. Suckowii*, of which *Cal. Cistii* formed the part above ground.—Application of the method of Poinsot to non-Euclidian statics, by M. J. Andrade. —Statics and the geometry of Lobatchefsky, by the same.—On the calculation of the resistance of the air to a disc for a velocity of twenty metres per second, by M. P. E. Touche.—On a propelling system for boats, by M. Y. Le Guen. — On the cosmic force curve, by M. Baraduc. — On isometric surfaces, by M. A. Pellet. — On small periodic movements of long-period systems, by M. P. Painlevé. — A mercury interrupter for large Ruhmkorff coils, by MM. E. Ducretet and L. Lejeune. The contact-breaker described, a figure of which is given, possesses the advantages of high speed, and certainty of break, without the danger of the alcohol igniting after long use. It admits of ready adjustment of speed.—On the dynamics of homogeneous chemical reactions, which take place with evolution or absorption of heat, by M. Michel Petrovitch.—Contribution to the history of the iodides of phosphorus, by M. A. Besson. Chemically pure PI_3 has been obtained by the action of dry HI upon PCl_3. It is completely decomposed by water without forming either free iodine or a solid deposit. The solution of PI_3 in carbon bisulphide is completely decolorised when shaken with an excess of mercury. The possible existence of an unstable P_3I_4 is also indicated, the existence of which gives a probable mechanism for the conversion of yellow into red phosphorus by iodine, the equations being $P_3I_4 = P_2I_4 + P$ (red), and $P_2I_4 + P$ (white) $= P_3I_4$.—On a method of oxidation and chlorination, by M. A. Villiers. The presence of a trace of a manganese salt accelerates many oxidations, as, for example, that of oxalic acid by a mixture of hydrochloric and nitric acids. This action is comparable with that of a ferment, and is of importance in vegetable physiology.—Breaking up of the fundamental band of chlorophyll, by M. A. Étard. By reducing the concentration of a carbon bisulphide solution of chlorophyll derived from *Lolium perenne*, the large band 729-635 splits up into three. This method of dilution, together with the superposition of two spectra in the same field, serves to show minute differences existing between chlorophylls derived from various sources.—On the oxidising action of manganous salts and on the chemical constitution of the oxydases, by M. Gab. Bertrand. The salts of manganese act as oxygen carriers to many organic compounds. The results are given of the action of various manganous salts upon hydroquinone in presence of air, and the theory is developed that these salts are partially hydrolysed into free acid and manganous oxide, that the latter takes one atom of oxygen forming MnO_2, and that the organic compound is oxidised by the remaining half molecule of oxygen. —Action of nickel upon ethylene. Synthesis of ethane, by MM.

Paul Sabatier and J. B. Senderens.—On isolauronolic acid, by M. G. Blanc.—Action of acetylene upon silver nitrate, by M. R. Chavastelon. According to the conditions of the experiment, either $C_2Ag_2.AgNO_3$, or C_2Ag_2 is formed.—Determination of resin oil in essence of turpentine, by M. A. Aignan. A portion of the oil is distilled and the rotatory power of the residue measured. It is notably reduced if the oil is adulterated.—On the active principles of some arums, by Mlle. J. Chauliaguet, MM. A. Hébert and F. Heim.—Action of albumoses and peptones in intravascular injections, by M. E. Fiquet.—On the relation of certain layers of lead carbonate to caves and ancient beds of subterranean rivers, by M. De Launay.—The characteristics of Broxburn oil shale, by M. C. E. Bertrand.—Classification and phyllogeny of the Goniatites, by M. Émile Haug.—On the Diceratineæ of the Tithonic beds in the Cevennes, by MM. V. Paquier and F. Roman.—On the Cueva del Drach (Dragon's Cave) in the Island of Majorca, by M. E A. Martel. This cave is in the Miocene limestone, and is the largest known in tertiary strata. It contains a subterranean lake 177 metres long, and from 4 to 9 metres deep.—Action of the X-rays upon the retina, by M. G. Bardet. The rays produce upon the retina a luminous impression which, although very faint, is quite clear.—Remarks by M. d'Arsonval on the preceding paper.—On the constitution of the large sympathetic nerve; its trophic centres, by M. J. P. Morat.—Experiments on the stimulation of nerves by the electric rays, by M. B. Danilewsky.—On a very grave case of dermatitis following two applications of the X-rays, by M. G. Apostoli.—Local therapeutic action of high frequency currents, by M. Oudin.—The saprophytic form of human and fowl tuberculosis, by MM. Bataillon and Terre.—On the influence of the hypnotic sleep upon the gastralgia of the dorsal tubes, by M. Ed. Spalikowski.—On the results of meteorological observations made in Marchuria and in the neighbouring countries, by M. Michel Venukoff.—On the variation of the surface temperature in soils of different natures, by M. Joseph Jaubert.

NEW SOUTH WALES.

Linnean Society, April 28.—Prof. J. T. Wilson, President, in the chair.—On the fertilisation of *Eupomatia laurina*, by Alex. G. Hamilton. Fertilisation appears to be effected by a small Curculio (an undescribed species of *Elleschodes*, specimens of which are now in the hands of the Rev. T. Blackburn for description), myriads of which, attracted by the scent of the newly-opened flowers, crowd the blossoms to the exclusion of other insects. They feed on the staminodes, eating their way into the heart of the flower. Microscopic examination of individual beetles taken at random showed that the antennæ, tarsi and other parts were coated with pollen. Robert Brown conjectured what happened, but did not see the beetles. Dr. Harvey saw the latter, but he appears not to have published any particulars.—Descriptions of the nests and eggs of three species of Australian birds, by Alfred J. North. Descriptions were given of the eggs of *Cracticus rufescens*, De Vis, from the Herbert River, Q.; *Sphenura broadbenti*, McCoy, from the Otway Forest, Victoria; and *Dendrocygna eytoni*, Gould, from the Macquarie River, N.S.W.—On some new or little-known Australian fishes, by J. Douglas Ogilby. Two new genera were characterised, and ten species of fishes were described as new.—On the development of the Port Jackson shark (*Heterodontus Phillipi*), Part I. early stages, by Dr. W. A. Haswell, Challis Professor of Biology, Sydney University. The hope is not unreasonably sanguine that the embryonic development of a type so ancient as *Cestracion* (*Heterodontus*) might exhibit some important primitive features. With regard to the stages now described, however, any expectations of this kind cannot be said to have been fulfilled; and what impresses one most in the results is the extraordinary persistency of certain characteristics which are not known to have any vital significance. There can be little doubt, for example, that the orange spot, which forms such a striking feature of the egg of an Elasmobranch in its early stages, has been handed down with but little change from Palæozoic times.—Description of a new Helix, by C. E. Beddome. The new species is near *H. mossmani*, Brazier, in its markings, but differs in being umbilicated and white-lipped. *Hab.*, Yeppon, near Rockhampton, Q.—Descriptions of new species of Australian Land Planarians: with notes on collecting and preserving, by Thomas Steel. Seven species of *Geoplana* from New South Wales and Queensland were described as new.—Descriptions of new species of Fijian Land Planarians, by Thomas Steel. One species of *Geoplana* and one of *Rhynchodemus* were described as new; and *Bipalium kewense*, Moseley, was recorded as common under logs on the Navua River, Viti Levu. Mr. Steel exhibited a fine collection of well-preserved and displayed Land Planarians, representing the species described in his paper, and illustrating the modes of preservation and the results after the use of the various preservative media advocated therein. Mr. Steel also contributed the following note on *Peripatus*. "I desire to place on record the occurrence in New South Wales of *P. oviparus*, Dendy, the Victorian form of *Peripatus*. While collecting in January of this year, between Exeter and Bundanoon (Moss Vale District), on turning over a log, I noticed a *Peripatus* which, from its attitude and general appearance, specially attracted my attention. This proved to be a female specimen of the above species, and, so far as I am aware, this is the first occasion on which its occurrence in this colony has been definitely recorded. The lozenge-shaped pattern which characterises most of the specimens found in Victoria is well displayed; and the fact of the ovipositor being fully extruded in the specimen, which I now exhibit, is sufficient guarantee of its identity. When visiting the Australian Museum a few days ago, I had an opportunity of examining the specimens of *Peripatus* preserved there, and I was interested in noticing that those collected by Mr. Helms, in 1889, at Mount Kosciusko belong to the same species. All of the females in the Museum collection from that locality, which I examined, have the ovipositor plainly visible, and in many of them it is fully extruded."

LAKES RUDOLF AND STEFANIE.

Through Unknown African Countries. The First Expedition from Somaliland to Lake Lamu. By A. Donaldson Smith, M.D., F.R.G.S., Hon. Member of Acad. Nat. Sci., Phil. Pp. xvi + 471, with illustrations and five-sheet map. (London: E. Arnold, 1897.)

THE region of Africa to the south of Eastern Abyssinia has been long regarded as of exceptional interest, both by the naturalist and the novelist. So early as 1847, when most geographers still believed that the snows of Kilima Njaro were a traveller's tale, and before Kenya had been seen by a European, Captain Short returned from the Juba, and asserted the existence of snow clad mountains away to the westward. According to the statements of some native traders to the court of Abyssinia, the bamboo forests of the same region were inhabited by tribes of dwarfs; and these reports were published by Captain Harris in 1844, long before the measurements by Schweinfurth, the skeletons sent home by Emin, and the discoveries of Stanley had called prominent attention to the pigmy races of Equatorial Africa. At a subsequent period, the late M. Abbadie placed a great mountain in the same unvisited district, exaggerating its height, as he recently naïvely remarked, in the hope of calling attention to it. Suahili traders also reported the existence in this region of two great lakes, of which the larger was sometimes called Samburu, and at others was confused with Baringo; it was the hope of reaching this lake region that led to the expedition of Burton and Speke, which came to such a disastrous end at the landing-place near Berbera. The excitability of the Somali, and the fascination of the discoveries made in East Africa south of the equator, subsequently diverted attention from this region, and it was not until 1888 that the first Europeans reached it. Teleki and Höhnel then entered from the south, and found, as reported, that there were two great lakes: the larger was named by its discoverer Lake Rudolf, apparently on the principle of Oliver St. John's dedication of his memoirs to Cromwell, who, by persuading him to travel, had given him the leisure in which to write them. After Teleki's return, several attempts were made to reach the twin lakes from the north, along Burton's projected route. But it was not until 1895 that success was gained by the expedition described in this volume.

The author, Arthur Donaldson Smith, is a young American doctor who prefers sport to surgery. He made a preliminary excursion in Somaliland in 1893, in order to gain experience of the people and the conditions of travel. Having further prepared himself by a course of training in geographical surveying, under Mr. Coles, he returned to Berbera in June 1894. He was accompanied by two English companions—a young sportsman, Mr. F. Gillett, and an experienced taxidermist and collector, Mr. Dodson; both of them gave him most loyal assistance. A force of 82 Somali were enlisted, and 84 camels purchased. The expedition started from Berbera on July 15; Dr. Smith had the advantage of the help of the most famous of African caravan headmen, the late Dualla Idris, who is, however, referred to as Haji Idris. The expedition crossed Somaliland to Milmil, and thence struck westward, and somewhat southward, in the hope of traversing the countries of the Arussa and Janjam to Lake Rudolf. The Webi Shebeli was crossed on September 1, and its course followed to a Galla settlement round the remarkable tomb of Sheik Hussein (the Scech Uscen of Bottego). The native tradition as to the origin of this building is clearly a legend, and more information about it would have been welcome. While staying here, Dr. Smith heard that the Abyssinians were in force at Ginea, a town a little distance to the south Mr. Gillett went to ask the chief for permission to proceed; but after considerable negotiations, during which the Abyssinians were friendly, the permission was refused, and the expedition had to return to the Shebeli. It descended this river to Bari, the village reached by the brothers James and Lort-Phillips in the first crossing of Somaliland. Thence the persevering explorer again turned westward, crossed the Juba, and marched over the Borana Galla country to Lake Stefanie. After exploring this lake, and the district to the north, the expedition continued westward to Lake Rudolf. Dr. Smith followed the course of the river that flows into the northern end of the lake for 75 miles. The river was apparently about to turn to the north-east, but he could follow it no further; and thus it is still uncertain whether the Nianam is the lower part of the Omo. From Lake Rudolf the expedition marched southward, across the waterless wastes of the Rendile country to the Nyiro, and descended the valley of the Tana to the coast.

The narrative of the journey is of great interest throughout. It abounds in sporting adventures, which are tersely and vividly told. The author had narrow escapes from elephants, rhinoceros, and lions. He came into conflict with hostile tribes on one or two occasions; but it was apparently not his fault. African natives are often fools, and it is impossible to read the narrative without feeling that there was nothing the author wanted more than peace. He had diplomatic intercourse with many "kings" and one "emperor," and throughout all his varied experiences he showed himself a man of resource, of courage, and of indomitable perseverance.

The scientific results of the expedition were very important. The five-sheet map, based on an extensive series of astronomical observations, is very valuable. The zoological collections were rich, especially in vertebrates; they are described in a series of appendices by Dr. Günther, Mr. R. I. Pocock, Prof. Jordan, and others, whose names might well have been given in the list of contents as well as the titles of their contributions. The collection of birds was, however, the most important, though there is no report upon it, and there is no complete reference to Dr. Sharpe's paper in which it was described. The general value of the zoological collection lies in the fact that it comes from the unexplored area between southern Somaliland and northern British East Africa. Many of the separate observations are also of interest. The author describes an attack made on a lion by some hyenas; he notes the existence of a large rhinoceros differing from the common species in the shape of the front part of the head. This animal has been recorded twice previously, but it is apparently still represented in Europe by a single horn.

 K

The principal geological problem, which it was hoped the expedition would settle, was whether the Omo Valley is a continuation of the great East African Rift Valley, in which Lake Rudolf lies. Unfortunately the circumstances which prevented Dr. Smith tracking the Nianam further towards its source are responsible for this question being left open. Dr. Smith, however, believes that the Omo is one of the head streams of the Juba, and does not flow into Lake Rudolf, as is generally believed from Borelli's work. If the altitudes given us are correct, the new view is impossible. Borelli descended the Omo to the level of 3450 feet: Bottego ascended the Juba to a height of over 4500 feet: the Omo cannot flow 1000 feet up hill into the Juba. Another alternative was once possible. We have previously suggested, from Dr. Smith's preliminary map, that "it is just possible that the Omo reaches this lake [Abaya] instead of Basso Narok [*i.e.*, Lake Rudolf]" [Gregory, "Great Rift Valley," p. 258]; but now Dr. Smith fixes the height of Lake Abaya as 3460 feet, so that the Omo is excluded from that goal. Hence, we are driven to the conclusion that the Omo must continue as the Nianam, and flow into Lake Rudolf, as Borelli believed; this conclusion is in agreement with the altitudes and with the trend of the country as shown by Dr. Smith's map.

Another point of interest to geologists is the evidence as to the existence of volcanic activity in this region; for Dr. Smith tells us that the Teleki volcano at the southern end of Lake Rudolf, in August 1895 "sent up clouds of smoke, and at night a great stream of glowing lava could be seen pouring from one of the craters" (p. 333). This information is especially interesting, as Mr. Neumann found no signs of activity there, and as the oft-asserted "Volcano Doenyo Ngai" now turns out not to be a true volcano.

In one respect Dr. Smith's information is strikingly different from that of Teleki and Höhnel. These explorers found the water of Lake Rudolf so brackish that they could hardly drink it, while that of Lake Stefanie was so salt that it was quite useless, and they could only stay on its shore owing to the existence of pools of rain-water. This was in 1888. But in 1895 Dr. Smith found the water of both lakes was quite fresh, in which he is confirmed by a very accurate observer, Mr. A. H. Neumann, for the northern end of Lake Rudolf. There can be no doubt that a remarkable change in the salinity of these lakes has taken place in only seven years; and the possibility of such changes must be borne in mind in considering the origin and relations of the African lake faunas. For example, it has been urged that the marine origin of the Tanganyika fauna is impossible, since there is no trace of marine influence in that of Lake Nyasa, through which the former, on the usual theory, must have passed. But Lake Stefanie reminds us that either a too rapid freshening of a lake, or a period of intense salinity, may obliterate the original fauna. Hence the complete absence of any marine types from the fauna of Nyasa is no proof that that of Tanganyika had not a marine origin. It should, however, be remarked that we are not expressing any acceptance of the view that the fauna of Tanganyika has any marine characters; but only that one of the arguments against that view is invalid.

The part of the book most open to criticism is that dealing with ethnography; but the facts mentioned show that the country traversed is of extreme interest. The author found some dwarf people about five feet high, and gives us a list of their words, although a few phrases would have been more useful; he describes some wells, which he attributes to the ancient Egyptians: and he met with Midgans, Tomal and "half-caste Boran," respecting each of which more detailed information is desirable. One quaint slip in this department is speaking of a "tamasho (*sic*) or equestrian exhibition" as though it were a Somali word instead of Hindustani for a "function." But one man cannot do everything; and now that the author has shown the way, we hope that other travellers will follow and collect further information regarding the many questions which the volume raises. For it is a great testimony to the interest of the country that Dr. Donaldson Smith's valuable book suggests as many problems as it solves.

J. W. G.

EXERCISES IN PHYSICS.

Problems and Questions in Physics. By C. P. Matthews and J. Shearer. Pp. vii + 247. (London: Macmillan and Co., Ltd., 1897.)

THIS useful book contains more than thirteen hundred problems in the various branches of physics, and, from the point of view of degree work, covers the ground required for the London Matriculation and Intermediate Science Examinations, as well as part of that for the Final B.Sc. It is, however, intended for all students of elementary physics, including, therefore, students of engineering, and the peculiar needs of the latter have also been provided for.

The authors begin with an introduction, which, as they explain, is intended not only to be read, but continually referred to, and contains short sections on physical measurement in general, units, vectors, the expression of physical relations by curves, averages, and approximations. A few examples are added on graphic methods, as well as a list of units and physical constants for use in the problems. Next follow the problems themselves; and the book ends with a set of four-figure mathematical tables, the solutions to the problems, and a rather meagre index.

In a work designed for students of both engineering and physics, one naturally looks first to see what is said on the vexed question of the unit of force. We congratulate the authors on the line they have here taken. As they explain in their preface,

"Many of the students who will use these problems are pursuing engineering courses. In such case, they must of necessity use engineering units. The aim has been not so much to train them in the use of these units—an abundance of this training comes to them during their course—but to bring out the relation of the so-called practical and gravitational units to the C.G.S. units of physics."

The C.G.S. and foot-pound-second systems are first defined, and the superfluous character of the latter tacitly assumed. This is shown by the fact that, after its definition has been given, the word poundal does not again occur. The authors then explain that pound and kilogramme are used by engineers as names for units of

force, and the two corresponding gravitational systems are well illustrated by problems introduced, throughout the mechanics section, among those on C.G.S. measurements.

This takes us as far as is at present, perhaps, possible in the direction of a compromise to which many teachers of physics are now looking forward—the recognition, namely, of two distinct systems of measurements only; one the C.G.S. with its derived practical system, for scientific and electrical purposes, the other the system used by engineers, and based on the units of length, time, and *force*.

Among other noteworthy features is a good set of problems on dynamos and alternating currents, another on wave and harmonic motions in connection with sound, and a third on gravitational potential in the section on work and energy. Less commendable, however, is the reference to water-levels in connection with electrical potentials. The most perfect "water analogy," and the one which, in our experience, appeals most directly to students, is that in which conductors are represented by water-filled cavities in a large block of india-rubber; it affords, indeed, almost the only means of enabling the average beginner to realise how the potential of a body or of a point in space may be altered by altering the charge on another body at a distance.

It is a pity that those problems which admit of solutions are not all supplied with them. Many are of the nature of examination questions, requiring long answers in words, and to these, naturally, no answers are given; but of the rest, not more than about three-fourths are solved.

We have noticed the following slips. The answers to Nos. 251, 759, 775, 776, 837 are either wholly or partially wrong; in No. 607 the water-worth of the dish should be given; and the headings to pp. 204 and 221 want altering. These are, however, small blemishes on an otherwise very useful work. A. P. C.

COSMIC ETHICS.

Cosmic Ethics; or, the Mathematical Theory of Evolution. By W. Cave Thomas. Pp. xxii + 296. (London: Smith, Elder, and Co., 1896.)

IN styling his book "Cosmic Ethics," Mr. Cave Thomas means to imply that not only in morals as a department of "the wider hygiene," but throughout the universe, there is but one law of rightness, that of balance, proportion, or the mean. By "mathematical evolution" he desires to signify that evolution is "the becoming of the proportioned," its goal being "the at-mean-ment of nature."

Starting from the admitted applicability of the idea of quantity throughout the concrete world, and from the progress which the sciences undoubtedly make when measurement or quantitative formulæ can be used in them, Mr. Thomas advances to an apotheosis of the average, and offers principia of the science of proportion and applications of quantification throughout the whole range of human knowledge. By somewhat elementary numerical formulæ we can determine the beau-idéal in the arts, attain to a quantitative ethic, discover that a man ought to drink neither too much nor too little, that his morning tub should not vary much in temperature from that of the human body, that the combination of great athletic and great intellectual effort leads to a break-down, and that technical and specialist education is inferior to general education.

Of the principia we may quote as an instance: "*The mean of fraction* is $\frac{1}{3}$; it is the fraction which is equally indifferent to the two extreme fractional limits of $\frac{1}{1}$ and $\frac{1}{0}$." (!) Of the exemplifications of the formulæ, we may point out that they are purely arbitrary. We ought to aim, we are told, at not diverging from the average, which is the ideal, to any extent which carries us beyond the middle third of our scale. Why not the middle fifth or seventh? There is no attempt to point out how the qualitative kind to which any particular scale is applicable is determined, and this despite of the fact that in a quotation which he makes from Reynolds—one of a constantly recurring set of quotations—that point is definitely raised.

Mr. Thomas accepts the Darwinian theory, though how the importance which that theory ascribes to "accidental variations" from type, can be reconciled with his own views as they stand, it is difficult to see. In fact, as they are here put before the reader, Mr. Thomas's doctrines will not allow of being harmonised into an intelligible system. This is the more to be regretted, as there is no doubt that an adequate elucidation of the theory of quantity, number, and measurement, would be of very great service to applied science. Nay, it is perhaps not too much to say that from the Galton system of composite photography, and from the statistical results of anthropometry, to which the author refers, conclusions of considerable value for art may be drawn. But they are not those drawn by Mr. Cave Thomas, nor to be drawn by his methods; though his considerable judgment in art and his grasp of the distinction between the organic fitness of an object for its purpose and its appositeness to human taste, make this department of his investigations the least unpromising.

His quotation of the headings of the chapters in Aristotle suggests the suspicion that Mr. Thomas has not studied that author in the Greek. Otherwise the attribution to him of a system of quantitative ethics would be, despite of the great authorities for that view, less pardonable than it is. Yet to the Greeks Mr. Thomas has chosen to go in his quasi-Pythagorean glorification of quantity. H. W. B.

OUR BOOK SHELF.

The Flora of the Alps. By Alfred W. Bennett, M.A., B.Sc., F.L.S. 2 vols., with 120 coloured plates. Pp. xxii + 165; vi + 223. (London: J. C. Nimmo, 1896.)

THE Alpine wanderer will not be very grateful to Mr. Bennett and his publishers for this new "Flora of the Alps." The net is spread widely; for, in addition to the whole Swiss flora, there are included here plants from adjacent mountain districts, and also the Pyrenees. The result is a rather cumbrous affair, and yet unsatisfying in detail. The species of each genus are enumerated with very short and sometimes rather inadequate characters, so that the identifying of specimens is not always as easy as it might be. That the book is arranged according to the system of Bentham and Hooker we may regard as a welcome innovation in Alpine floras, which have been too long wedded to the irritating Linnæan system. The

paper and printing are in their way admirable, but the thickness of the former does not make for portability. The custom of arranging Latin and English names under separate indices should be prohibited. It is a time-honoured survival in some Floras, but a constant source of annoyance to their users. Whether the 120 coloured plates of Alpine plants scattered through these pages will prove acceptable to purchasers of the work, we cannot say. A very large number of them are to be found in Wooster's "Alpine Plants," published a quarter of a century ago, though we have searched in vain for any indication of this fact. Then, too, some trouble was taken in the printing, and the result was not unpleasing. In Mr. Bennett's "Flora," these old plates have been mutilated, as will be obvious to any one who cares to compare the two works. In these days of modern methods and high-priced books we expect an advance, not a retrogression. We have said sufficient to show that the ideal Alpine Flora still remains to be produced. Our own view is that it should be somewhat on the lines of Hooker's "Student's Flora of the British Islands," with a separate volume of woodcuts similar to those of the well-known "Companion" to Bentham's "Handbook." If coloured plates are wanted, a draftsman of high artistic capacity and requisite botanical knowledge must be employed, whilst the printing must be of the very best. Nor would the public which travels in the Alps, and collects and examines the flowers growing there, be backward in its recognition of such a work.

First Stage Mechanics of Fluids. (The Organised Science Series.) By Prof. G. H. Bryan, Sc.D., F.R.S., and F. Rosenberg, M.A. Pp. vi + 208. (London: W. B. Clive, 1897.)

IN the pages of this book the authors have brought material together to cover that part of the subject of mechanics which is required by the Science and Art Department in the elementary examination. There are also chapters devoted to that portion of dynamics which is required by the corresponding syllabus in the mechanics of solids. The twenty-three chapters which fulfil the above-mentioned requirements are so arranged as to form an excellent elementary treatise, and also a good introduction to those who wish to make a further study of the subject. The style of treatment is similar to that adopted in other books of this series. The authors advocate strongly the importance of each student working out examples by himself, and with this idea have inserted numerous solved and unsolved problems. They have also kept down the number of formulæ, in order that the reader shall attack problems from first principles, and not trust to his memory; for those formulæ which have been inserted, proofs have been added. Numerous typical illustrations and figures are inserted in the text, thus rendering it still more serviceable to the young beginner.

Illustrative Cloud Forms. By C. D. Sigsbee. (Washington: U.S. Hydrographic Office, 1897.)

IN this book we have a collection of coloured plates, sixteen in number, illustrative of the different typical forms which clouds assume under various conditions. The classification, nomenclature, and descriptive text are derived from the "International Cloud Atlas" (Paris, 1896), but the plates are from the original paintings made for the Hydrographic Office by Mr. Rudolf Cronau. In addition to the ten standard types which are included in the classification, six further plates are devoted to illustrating certain modifications of these, such as fracto-stratus, fracto-cumulus, mamato-cumulus, &c. Each plate embraces the horizon and sufficient extension of view, so that the observer can obtain a good idea of cloud perspective. The paintings themselves have been made as accurately and as true to nature as possible, and photographs, printed exemplars, together with the artist's personal observations and knowledge of clouds, have all been brought to bear on them. Great pains have been taken by the Hydrographic Office to ensure a faithful reproduction of the originals, and we can safely say that the observer has here before him a most excellent guide for the classification of clouds, which branch of meteorology is becoming every year of more importance as a means of forecasting the weather.

Among British Birds in their Nesting Haunts, illustrated by the Camera. By Oswin A. J. Lee. Part iv. (Edinburgh: David Douglas.)

THE first three parts of this work were noticed in these pages a few weeks ago (May 13, p. 26); the photographic reproductions in the present part are as attractive as those which preceded them, and will interest every student of bird life. There are ten large plates showing the nests of the Woodcock, Oyster-catcher (two plates), Tree Pipit, Reed Bunting, Ringed Plover (two plates), Little Tern (two plates), and Jackdaw. Brief notes upon the birds and their nesting haunts accompany each plate.

More brilliant photographic pictures of the nests of birds have never been published than those which now bear testimony to Mr. Lee's skill with the camera. The work in which the pictures appear is already known to most ornithologists, and it will long receive a full measure of admiration.

The Indigenous Drugs of India; Short Descriptive Notices of the Principal Medicinal Products met with in British India. By Kanny Lall Dey, Rai Bahadur, C.I.E. Second edition. Pp. 387. (Calcutta: Thacker, Spink, and Co.)

A WORK like the present, which is intended to promote the extension of our knowledge of Indian drugs, is much to be welcomed. Indian Materia Medica presents a wide field of research for the botanist, chemist, and pharmacologist. Dr. Lall Dey's book is a useful epitome of the characters and uses of Indian indigenous drugs, and contains a great deal of valuable information. It will form an excellent introduction to larger works on the subject, such as Dymock's "Pharmacographia Indica," and Watt's well-known Dictionary.

LETTERS TO THE EDITOR.

The Storm in Essex on June 24.

I AM doubtful if an English thunderstorm has ever assumed the proportions that one reached here on Thursday last. Although there is nothing new under the sun, yet there is a good deal new to each individual, and the following facts were not looked on as possibilities by me before I witnessed them on that day.

The 24th was an intensely hot day, and after much distant thunder the storm broke on us about 2.45 p.m. (while haymaking was in full swing) from the north-west. After about ten minutes of the heaviest rain, hail began to fall, and soon a terrific hurricane, accompanied by hailstones larger than hens' eggs (mixed in with others of all sizes downwards), came on and lasted for five minutes, during which most of the damage was done. After this the storm gradually abated, and in something over half-an-hour had passed away. The scene was quite unique and winter-like. The ground was quite white, and in many places the hail had drifted to a foot deep, and every ditch and depression in the ground was full of water and hail. Every

window on the north-west sides of the houses and cottages was destitute of glass—not merely broken, but the whole driven through. Two greenhouses were completely smashed, only one pane in some miraculous way having escaped on the windward side. A bird-cage hanging in a window was demolished, and the bird found in a chair on its back under a bit of glass. Rooks and pigeons were lying about the fields dead and dying, and one of my men secured enough for a rook pie next day. Also we picked up next day some half-dozen small birds while turning over about eight acres of hay.

A stable roof covered by pantiles half-an-inch thick had half the tiles broken into quite small pieces, and has the appearance of having been shot at by rifles. Several chimney stacks had been blown on to the roofs, and in one case close by, through the house to the ground. All the farm buildings and cottages were unroofed more or less.

Trees had fallen in quantity, either torn up by the roots or broken off in the middle. Branches had been twisted off everywhere and hardly a leaf remained; the neighbouring common was beaten down as if an army had stampeded over it.

The crops presented a curious and melancholy sight. The grass intended for hay looked as if a steam-roller had been over it. The oats had also been not only beaten flat, but broken off short, and reduced to a sort of long chaff; in some cases the ends of a piece of stem stuck up, while the middle had been driven into the ground by a hailstone.

The mown ground and the lawn were indented to the depth of from one to two inches all over, much as if a flock of sheep had passed over them. This was, of course, also seen on the flower-beds and mangold-fields. This last crop has also been destroyed to the extent of two-thirds, every leaf broken off, and often the root in two pieces.

A hedge at right angles to the storm and some wall fruit were completely stripped of leaves and twigs, and left with "bare poles" nearly half denuded of bark; not a vegetable remains in the garden. Luckily the area of greatest severity was very small and not in the centre of the storm. The advancing front of the worst part seems to have been only about a mile in width, and to have spent its greatest energy after advancing a like distance.

The hailstones were in appearance a conglomerate of smaller ones cemented together with ice, and generally the centre stone was bigger than the others. They were much collected together in corners, and one was measured, twenty-four hours after the storm, four and a half inches round. SHEFFIELD NEAVE.

Ingatestone, June 28.

On Mimicry.

DR. JORDAN'S suggestion (p. 153) that the result of a one-sided selection involves a physiological one-sidedness unfitting a mimetic species in other respects for the struggle for existence, can hold good only if the selective change in external imaginal characters be correlated with an unfavourable modification of other characters, perhaps in another stage of the insect's life; inasmuch as destruction can modify a species solely in respect to the constants for which it is selective.

Unless such correlation can be shown to exist, the physiological one-sidedness postulated by Dr. Jordan remains as hypothetical as are still many of the axioms on which the existing theories of mimicry are supported.

His objection is precisely analogous with another which is sometimes advanced: that the process of selection towards mimetic resemblance of the imago is rendered nugatory by means of the enormous destruction of individuals in the early stages, and the consequent survival of a very small percentage to hand on the greatly diluted effects of selection. But if the imagos of a mimetic species are distributed about a mean in respect of the degrees of likeness to a model, it is clear that no amount of unselective destruction, *i.e.* one which reduces the numbers uniformly on each side of the mean, can modify the curve of distribution.

That is, no loss of larvæ or pupæ can lessen the force of imaginal selection, unless there be correlation of characters.

Dr. Jordan's suggestion, however, is complementary to one at which I have arrived, but which I have hitherto put forward only privately. Even if there be no correlation of characters, as he assumes, a limitation upon the numbers of a mimetic species may yet be due to interrelation between its abundance and the natural checks upon its multiplication.

If a species, hitherto non-mimetic and persisting in small but constant numbers, come under the influence of a "protected" model, and the distribution of mimetic forms shows that such a phenomenon has probably been common, it must escape destruction in the imago stage in proportion to the degree of resemblance thereby acquired.

If the natural checks on its earlier stages remain constant in ratio, the mimic must become increasingly numerous concomitantly with increase of likeness to the model, the effect on which, though important, need not now be discussed.

But it is possible that, apart from any physiological modifications, the greater abundance of the imago is counteracted by increased destruction in other stages. While the effect of climate, for example, is presumably constant in ratio whether the species be few or numerous in examples, it is almost certain that within limits such important checks as animal parasites (Ichneumonidæ, &c.) become actually more efficient with multiplication of the host. In other words the number, say, of larvæ which can exist in a given area may be limited by such outside causes; so that no amount of lessened destruction of the imago can cause the species to become more numerous, because it is counterbalanced by greater larval destruction. And if the species has a greater chance of survival in the imago stage, it may actually become rarer therein as a result of the necessity that the number of larvæ shall remain constant.

If this be the case, mimicry may indeed be the outcome of natural selection; but, as Dr. Jordan suggests, it may have nothing to do with utility or the survival of the species.

And this leads to a further generalisation: it is conceivable, and indeed probable, that many species can exist indefinitely in small but constant numbers, as rarities, that is, which are unable by the assumption of any favourable modifications to become permanently common, owing to the interrelation of the factors which impose a limit on their multiplication.

June 19. WALTER F. H. BLANDFORD.

A Bacterium living in Strong Spirit.

IT is well known that the shipments of rum from Demerara, especially during the past year, have been "faulty," and very great pecuniary loss has resulted to the colony. Through the kindness of a friend and the courtesy of the Excise authorities, we received certain samples direct from a bonded warehouse; we were informed that the spirit had been returned at 42 per cent over proof, equivalent to 74·6 per cent. alcohol by weight; our determinations showed the assessment to be correct. On microscopical examination of a sediment at the bottom of the samples, using a magnification of 1200 diameters, we found chains of small cocci; after the spirit had been kept for some days the cocci were seen to be surrounded with a gelatinous envelope, and after a further interval of time the cocci were found disseminated throughout the liquid, and were rapidly developing and multiplying. The micro-organism, adopting the classification of Zopf, belongs to the group Coccaceæ, and for the present, from our study of cultivations, we are inclined to regard it as a new species; we have already obtained several stages of its life-history, and hope shortly to be in a position to publish a fuller account of its development and the chemical changes which it produces. Meanwhile, the observation of the existence and multiplication of any micro-organism in a spirit of such alcoholic strength appears to be of so much scientific interest, and the problem of its presence of such technical importance, that we send this note as a preliminary communication.

Oxford, June 23. V. H. VELEY.
LILIAN J. VELEY.

A Well-known Text-Book of Chemistry.

YOU have thought proper to admit to your columns a long and rambling notice of my "Manual of Chemistry," by Mr. M. M. Pattison Muir. It is difficult to make out from this what, definitely, is the charge which the writer brings against the book, but the article winds up with the statement that in his opinion "this book is not a success." I have the satisfaction of believing that chemists will derive little except amusement from this expression of Mr. Muir's opinion; but, as presumably NATURE is read by a portion of the general public and by some scientific persons who may not be acquainted with Mr. Muir's chemical idiosyncrasy, I desire to say, more in the interests of

my publishers than of myself, that this opinion of his is not shared by the writer of any one, so far as I have seen, of the notices which have appeared in other papers.

WILLIAM A. TILDEN.

Royal College of Science, London, June 19.

The Gravitation Constant.

I BEG to point out that at the end of the article on pp. 127–128 of NATURE, relating to my researches on the gravitation constant, there is a misprint. The "oscillation" result for 1892 should be 5·523 instead of 5·520.

The error is not great, but by correcting it a much better concordance appears between the four principal values.

CHARLES BRAUN.

Mariaschein in Bohemia, June 21.

THE AMERICAN EXCAVATIONS IN SOUTHERN BABYLONIA.

FOR the last fifteen or sixteen years we have been glad to watch the endeavours of the Americans to carry out systematic excavations in Southern Babylonia, and we feel sure that all will rejoice with them now that they are able to report a very considerable success. It will be remembered that the first American to visit that country with a view of acquiring antiquities was Mr. Hayes Ward, who went out there early in the "eighties"; and the report which he gave on the matter probably helped forward the later expeditions of Dr. Peters and Mr. Haynes. Dr. Peters and a small party of promising young men went to Baghdad in 1890, and set out from that city for the ruins of Niffer, which are situated a few days' journey to the south-west, where they began to dig. For various reasons, however, Dr. Peters withdrew from the work soon afterwards, and the Committee of Excavations of Pennsylvania University determined to place the undertaking in the hands of Mr. Haynes, then the American Consul at Baghdad. Mr. Haynes took over the work, and for some years past he has devoted all his time to it, through the heats of summer when the land is burnt as hard as a brick, and through the rains of winter and early spring when the plains become seas of mud, has he lived at Niffer, patiently digging through the ruins of the temple, and tower, and ramparts, and court-yard, and hidden chambers of that ancient city. No other excavator has done his work so thoroughly, or so well in consequence, for he never left his post whilst diggings were going on; and though the cuneiform scholar sitting in a comfortable chair at home reading the descriptions of the work by Dr. Hilprecht[1] may think lightly of such devotion to science, it by no means diminishes its value. Moreover, the Arab of the neighbourhood of Niffer is not the gentlest of men; on the contrary, when he is displeased with the "Frangi" excavator, he will break his water-jars, or slit his water-skins as they are passing on donkeys to the river, or try to burn down his tents, or even to kill him, as he has done to more than one excavator.

In the limited space at our disposal we do not intend to describe the details of Mr. Haynes' excavations, but only to call attention to the general results of his work and their bearings upon the early history of civilisation in the East. Like all the cities which lie between the Tigris and Euphrates below Hillah and Baghdad, the mounds of Niffer contain the ruins of a temple of considerable size and of a tower; both rested upon a solid clay platform, the intention of the architect being to lift the buildings which were to be set upon it out of the reach of floods and overflows of the river. Round these ran a wall more than fifty feet in thickness, the object of which was, naturally, to keep out foes from the temple buildings and tower. The ruins which Mr. Haynes found on the platform belong to the temple and tower which a king called Ur-gur built about 2600 B.C.; but below this, Mr. Haynes found another platform which Sargon I. had built some twelve hundred years earlier, for all the bricks bore the name of this king and of his son Naram-Sin. Digging down deeper, Mr. Haynes found the ruins of one or more temples, but there are no inscriptions or marks upon any object which will help us to date them. Elsewhere in the outlying buildings in the mound small but strongly built chambers were found, and it is thought that these were employed for the safe keeping of records, tablets, and the like. Thus it seems that the oldest inscribed object discovered at Niffer belongs to the reign of Sargon I., who, according to the information given on the famous Cylinder of Nabonidus, reigned 3200 years before that king's time. The question which will naturally be asked next is, "To what period do the temples, the ruins of which were found beneath Sargon's platform, belong? and who built them?" At present it is impossible to give a satisfactory answer. Those who would reckon years by the depth of deposits say these temple-ruins are about 2000 years older than Sargon's platform; but this is, after all, only a guess, and if probabilities are taken into consideration we might as well date them at 10,000 B.C. as 6000 B.C., and we deprecate the use of exact figures in such matters. What is to be considered is the fact that about 3800 B.C. Sargon was able to build such a strong fortress, and that all the faculties of civilisation which such a power implied existed at that remote date. As to the earlier buildings which he found there and the platform on which they rested, they probably only stood upon the ruins of earlier buildings and of an earlier platform, and the site of Niffer being favourable for a city, it is more than likely that one stood there from time immemorial. To attempt to limit a civilisation of such antiquity as that of Southern Babylonia by thousands of years is, in our opinion, futile; though figures are useful at times to convey to the non-expert a general idea of antiquity. Mr. Haynes has proved that Niffer, in common with Tell-Lo, was one of a number of large and important cities which flourished in Southern Babylonia between 4000 B.C. and 2500 B.C., and the materials which he has obtained will enable us to describe the knowledge and religion, and manners and customs of its people with a fulness and minuteness hitherto impossible. We trust that he will soon give us his own account of the work which he has carried out, and meanwhile accord him our thanks for what he has already done, and congratulations upon the great success which he has achieved.

1 "The Babylonian Expedition of the University of Pennsylvania," vol. i., 1893; vol. ii., 1896. (Philadelphia: Reprinted from *Trans. Amer. Philos. Soc.*, N.S., vol. xviii., Nos. 1 and 3.)

THE FRESH-WATER FAUNA OF LAKE TANGANYIKA.

THE aquatic faunas of the great lakes of Central Africa, although like so many other features of the dark continent still largely unexplored, have attracted a good deal of attention during the last few years. It has been ascertained that some of these great sheets of water, although physiographically apparently so similar, are absolutely unlike each other in respect to the aquatic animals they contain. Thus the fishes and molluscs of Nyasa, which have been up to the present time by far the most completely known, show no forms which have deviated widely from easily recognisable fresh-water stocks, or that suggest that Nyasa has at any past time been more directly connected with the sea. On the other hand, one of the first items of zoological information which reached Europe concerning Tanganyika, was the discovery of a Craspidote medusa by Boehm in 1893. The mere existence of fresh-water medusæ is such a rare and remarkable occurrence, that scientific interest

became at once turned towards the Tanganyika fauna as a whole, and a re-examination of the shells of the molluscs of the lake, which had been brought home by various travellers, showed that the medusa was only one member of a remarkable fauna, many of the forms of which were as singular and marine-looking as the jelly-fish itself. Up to the present time, however, the real nature of this remarkable assemblage of lake animals has of necessity remained entirely problematical, since, without more material, it was impossible to attempt to determine whether the close similarity, which some of the gastropod shells exhibit to species living elsewhere in the ocean, was due to actual affinity, or was brought about by a convergence of variations induced somehow in an originally fresh-water stock. To obtain the material sufficient to throw light on these forms, by a determination of their actual affinities, was the object of an expedition to Tanganyika, which, through the generosity of the Royal Society and British Association, I was able to undertake nearly two years ago.

The only practical route at present open to the Lake lies up the great Zambesi water-way, which, but for the Murchison Cataracts, extends from the coast to the north end of Lake Nyasa. From this point it is necessary to march across the elevated forest land, and mountain ranges which constitute the interior plateau.

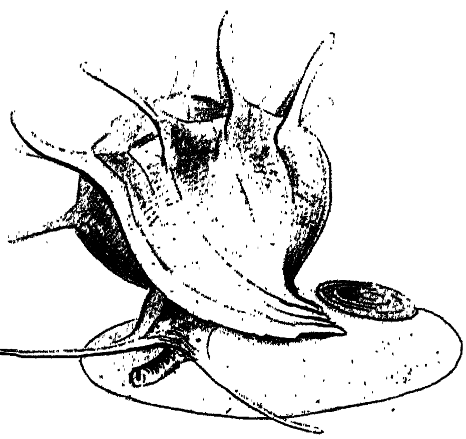

FIG. 1.—Living *Typhobia Horei.*

Approached in this direction the lake becomes first visible from the heights above Kituta, where a strip of bright green marsh-land skirts its southern coast. Descending from these heights the damp oppressive heat of Tanganyika is felt at once, and long before reaching the water's edge the forest is filled with the sickly scent which characterises the whole lake, and reminds one strongly of that of a weedy tidal beach. The lake has fallen considerably of late, and much of the coast-line is now obliterated by dense papyrus swamps, reeds, and partially submerged mimosa scrub, so that its actual shore is often very difficult to approach. In the deep water of this southern arm there are vast drift collections of empty Neothauma shells, which act as growing points for sponges, and constitute the feeding-ground of innumerable small active and entirely aquatic crabs. The living Neothaumas are found in shoaler water, generally on the flat sandy deposits which characterise the coast-line of other portions of the lake. Above the water's edge this sand has been thrown up by the wind and surf into low dunes, which are now covered with mimosa scrub and wild cotton, and beyond these, again, there is generally a strip of swamp swarming with Dactylethera, Ampularia shells, and frogs.

In many places, however, the mountains are not fringed by these lacustrine flats, and where the great western escarpments of the rift valley in which Tanganyika lies, rise perpendicularly from the water's edge, the submerged stones are covered with a bright growth of green algæ, and studded with numbers of the so-called Paramelania, a marine-looking gastropod, the affinities of which are not yet known. The great range of variation which these shells exhibit is most remarkable, and their differentation seems to be a simple function of the depth at which the shells exist, those with the most prominent processes being the lowest.

The different kinds of coast-line, which I have just described, are more or less characteristic of the whole lake, and each has a fauna peculiar to itself; but, on the flat sandy beaches, all sorts of shells, fish-bones, and the like are thrown up together by the waves, so that it is some time before one ascertains the habitat of each. Thus I observed the exquisite spined Typhobia shells two months before I found a specimen alive, owing to the fact that Typhobia, together with some curious associated forms, inhabit the profound depths of the lake, and are only to be obtained by dredging with lines of from five to seven hundred feet.

Like Neothauma and Paramelania, these deep-water gastropods are all viviparous; but while the first deposits

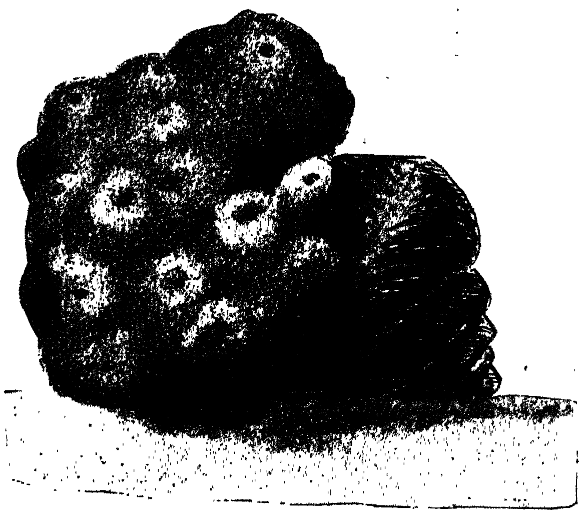

FIG. 2.—Sponge growing on dead shell of Neothauma.

only two or three large embryos at once, Typhobia produces a great number of bright green young. In this form all stages of development are present in the same animal, and we have, therefore, embryological material which may throw much light on the affinities of an aberrant group. It would be unprofitable for me, as yet, to enter into any discussion of the comparative morphology of these forms; but it may be interesting to note that, while the radula formula of Neothauma approximates in character to that of Paludina, that of Typhobia and its associates is almost unique, and although the Paramelanias show some similarity, in this respect, to the forms with which they have been provisionally associated, the radula of the so-called Lythoglythus of Tanganyika is absolutely unlike those of the forms to which it has been thought to belong.

Typhobia and its allies inhabit the flat mud bottom of the lake, and the mud itself contains numerous spiculæ, which, on treatment with nitric acid, are seen to be siliceous, many of them being indistinguishable from those of the sponge Potamolepis, found as an encrusting species in the Congo, but which I have not seen living in Tanganyika.

In many places the precipitous coast-line of the lake has been cañoned out by waves and storm-torrents into a succession of superb rocky headlands, and in the still waters of the recesses, which they partially enclose, there are innumerable swarms of prawns, some of which are certainly Palœmon-like in structure; but I am not yet sure of the affinities of them all. Like those of the Lago di Garda in Italy, lake prawns are generally supposed to have migrated up the rivers from the sea; but it is curious that they should have found their way 2700 feet up into Tanganyika, and yet not have reached Nyasa, which is so much nearer the coast.

It would be impossible within the limits of this article to give any account of the widely different forms of Tanganyika fish; but there is a curious and, I believe, quite new example of protective mimicry exhibited by a small chromis, which, in order to escape from the swarms of kingfishers along the shore, has simulated the bands of colour, size, and mode of swimming of a leech.

There appears to be only one species of medusa in Tanganyika; but this species, like so many of the lake animals, is subject to wide variation, and if the intermediate forms could not have been obtained, the extremes would certainly have been regarded as distinct species. They are rather local in their distribution, and are not always easy to find, but in some places they exist in countless numbers, and are seen at every depth, slowly pulsating after the manner of jelly-fish, till they reach the surface, and then sinking again motionless with their array of long tentacles standing stiffly up above the bell.

Towards evening the deep water of the lake is often filled with a finely-divided substance, that glitters in the sunshine like precipitated gold, and this appearance is found to be caused by the sculptured shells of swarms of Peridinia, together with a number of large infusoria, the broad bands of cilia and undulating membranes of which show them to be related to the Condylostomas. The appearance produced by this assemblage of pelagic protozoa is probably what Livingstone described in his last journal as a yellow scum on the surface of the lake, attributing it to some vegetable form.

The assemblage of animals which I have just described appears to be almost entirely restricted to the confines of the lake, and it is this geographical isolation to which at present I would draw attention, as it is, without doubt, among the most remarkable characteristics which the fauna possesses. In fact, the presence of such an assemblage of animal forms in an inland and greatly elevated lake is only intelligible by supposing either that the lake itself was at one time connected with the sea, and that its fauna is a collection of types which have persisted as survivals of an oceanic series that has elsewhere passed away, or that its marine characters are due to parallel development, produced in a fresh-water stock by the action of some conditions obtaining in an immense inland lake. I would at present offer no opinion as to which of these surmises is likely to prove correct; but whatever supposition may be entertained, it becomes obvious that the fauna of Tanganyika is comparatively old, for it is unlike anything now inhabiting the sea, and if it is derived from a previous fresh-water stock, much time would be required for the evolution of its widely-divergent present forms. This conclusion as to the comparative antiquity of the Tanganyika fauna is, in my opinion, the most important which can be drawn with certainty from a cursory survey of the facts; and, without attempting to push comparisons at present, the remarkable similarity between several varieties of Paramelania and those of the equally variable Jurassic genus Purpurina, between other varieties of Paramelania and the American and Southern European Pirguliferas, should be fully borne in mind. The determination of the actual affinities of the Tanganyika forms, which are often exclusively related to the lake, can only be made by a prolonged comparative study of the morphology of each, and it would be at present useless to speculate on the result. I have here only indicated some of the peculiarities of the fauna of the lake as they present themselves to a naturalist on the spot, the actual results of the investigation having yet to be produced.

J. E. S. MOORE.

THE LAWRENCE MEDAL.

WE are glad to be able to give a reproduction of a fine gold medal of Sir William Lawrence, now in the Royal Academy Exhibition, designed and executed by Alfred Gilbert, R.A. It forms part of a scholarship, founded in memory of Sir William Lawrence at St. Bartholomew's Hospital, and is given annually. The medal, cast and chased, $2\frac{1}{4}$ inches in diameter, shows the face and head in high relief, and gives striking evidence of the artist's skill, as the likeness well preserves the

dignity and intellectual power of the original. The view is nearly full face, not the usual profile, a treatment of which there are but few examples, either ancient or modern, and of difficult execution. The reverse has an allegorical subject suited to the aim of the scholarship, and instinct with the grace and fancy of which Mr. Gilbert is master. A youth, full of confidence, presses through the shield dividing him from life, whilst wisdom and science on either hand whisper counsel as they point to the motto on the shield, part of the line from Homer,

"αἰὲν ἀριστεύειν καὶ ὑπείροχον ἔμμεναι ἄλλων," often cited by the original of the medal.

A few notes follow, on a less well-known side of Sir William Lawrence's early work, from the pen of a distinguished pupil.

IN MEMORY OF LAWRENCE.

In the domain of surgery the name of Lawrence is held in high honour as that of a practitioner and observer of the utmost skill and originality. As a teacher at St. Bartholomew's Hospital and in the theatre of the College of Surgeons his services to the profession which he had adopted are recognised as having been invaluable. It is, however, not perhaps so well known that he was also a pioneer in those branches of research which more recently, under the direction of Darwin and Wallace, have effected such a revolution in our conceptions of the great scheme of zoological development. Not that it can be claimed for Sir William Lawrence that he anticipated the modern creed as to the descent of man, for he expressly repudiated the tenet of a common line of ancestry for man and brutes. Still, however, his lectures on the "Natural History of Man," delivered as professor to the Royal College of Surgeons, were far in advance of the opinions of the day, and were full of new thought and suggestion. They were published in 1816, and went through at least eight editions. Although now superseded by other works, they are still a mine of carefully collated facts to which the student refers with pleasure and profit. As is well known, they brought upon their author a storm of persecuting zeal, at the head of which was Abernethy, Lawrence's senior colleague at the hospital! In a second course of his college lectures Lawrence referred to these proceedings, and in a tone of manly independence claimed the right to think for himself and to express his opinions in his own terms. "These privileges, gentlemen, shall never be surrendered by me; I will not be set down nor cried down by any person, in any place, or under any pretext. However flattering it may be to my vanity to wear this gown, if it involves any sacrifice of independence, the smallest dereliction of the right to examine freely the subjects on which I address you, and to express fearlessly the result of my investigations, I would strip it off instantly." This was bold language in a young man, and one who in his profession was of course a candidate for public favour. It was indeed by this high endowment of moral courage that Lawrence was enabled to approach the topics which he treated of in a manner which was so far in advance of the current modes of thought, and so eminently advantageous to the age.

Lawrence's personal bearing was an index of his character. His stature was tall and his manner dignified, and his face was, in its expression of intellectual calm, one of the noblest ever worn by man. JONATHAN HUTCHINSON.

JULIUS SACHS.

JULIUS SACHS[1] was born at Breslau October 2, 1832, and died at Würzburg on May 29, 1897. Although his health had been seriously impaired for years, his last illness was not of long duration. He was regularly at work in his laboratory during the Easter vacation, and only took to his bed about the middle of April. A few days before the end came, he sank into coma and died without pain. Of his early career I have not been able to learn anything: I remember to have heard him say that his first teacher was Purkinje, under whom he published two or three zoological and geological papers. His first official post was that of Privat-Docent at Prague. In 1858–59 he was at Tharandt, in 1860 at Chemnitz. In 1861–62 he was appointed Professor in the Landwirthschaftliche Institut at Poppelsdorf, near Bonn. In 1867 he was called to the chair of Botany in Freiburg, and in 1867 he obtained the professorship at Würzburg, which he held up to the time of his death.[2]

It is not easy for a botanist of these days to estimate the debt of gratitude that he owes to Sachs. We have grown up in the modern school, and we mistake for our natural environment a state of things which his labour of forty years painfully built up for us. There is a natural blindness of the child to the parent, or the apprentice to his master, and this we can only partially overcome.

The place of Sachs in the history of Botany is, I am inclined to think, even higher as a teacher than as a discoverer. He will be more permanently known for his "Experimental Physiologie" (1866), by his "Lehrbuch" (first edition, 1868),[1] his "Geschichte der Botanik" (1875),[2] and his "Vorlesungen" (1882),[3] than by his "Collected Papers" (1892–93). The earliest of these volumes, the "Experimental Physiologie," seems to me in some respects the best. If we compare it with previous books on the physiology of plants we feel an enormous advance, not only in the fire and vigour with which it is written, but especially in the absence of compilation; it reads like an original paper rather than a treatise, and it was in fact largely founded on the activity of twelve of the best years of his life. Between 1853, when his first paper appeared in the Czechish journal *Ziva*, until 1865, just before the publication of the "Experimental Physiologie," he published (according to the Royal Society's Catalogue) sixty-eight papers, of which, however, the two or three earliest ones were not botanical. The book gives internal evidence of being written with the delight of a strong man in his work, and Sachs has been heard to say that he wrote it with a pleasure greater than that given by any of his later books.

On the other hand he spoke, if I remember aright, somewhat wearily of the years of section-cutting and microscopy needed for his "Text-Book." This may serve to remind us of what we are apt to forget—the mass of original matter hidden in this admirable book. In his last book, the "Lectures" of 1882, he returned to what best suited his turn of mind—a broad, general view of physiology. At the same time he handed over the re-editing of the histology, the detailed morphology and classification in the "Text-Book," to his friend and pupil Goebel.[4]

The "Text-Book" has no doubt had a greater effect on botany than any one of his other books. The modern botanist is sometimes assumed to be ignorant of taxonomy, but a man who has worked practically through Sachs' "Text-Book" knows more of the classification of the vegetable kingdom as a whole, than the older botanist who knew the phanerogams minutely, but little beyond them. As a single proof of the fruits arising from a proper understanding of the taxonomy of plants, it may be pointed out that palæobotany has only been rendered possible as a science by the sort of knowledge inculcated by Sachs. Witness the work of Solms Laubach and Nathorst and others on the continent, and of Scott and Seward in this country, as compared with the efforts of earlier workers. The effect of Sachs' "Text-Book" in England was intensified by the great revival of scientific teaching instituted by Huxley, in which the all-importance of practical work was insisted on. And thus the learner of those days had the good luck to be supplied with Sachs' "Text-Book" just when he was spurred on by his teacher and by the spirit of the times to examine the histology and physiology of plants for himself.

As a teacher in the laboratory Sachs' position was equally great. He was most generous in receiving pupils, and those of us who had the good fortune to be of that number must always remember with gratitude his genial welcome and the pains he took with us over our work. To some it was a first introduction to a research laboratory, to a region where, if examination is not quite

[1] I believe that Sachs never made use of the title of *von*, which was conferred upon him.

[2] For the above facts I am indebted to the kindness of Prof. Kunkel of Würzburg, and Prof. Marshall Ward.

[1] The English translation of a later edition appeared in 1874, under the name of "Text-Book."

[2] English translation, 1890.

[3] English translation, 1887.

[4] English translation, under the title of "Outlines of Classification, &c.," 1887.

banished, it is so much in the background as to be forgotten. It was extraordinarily invigorating to fall into the midst of a group of young men each engaged in his problem, and ruled over by a kindly despot full of resource and enthusiasm, and both willing and able to give us questions to solve. His tendency was to do things in a broad, handsome manner. He liked to have a flush of material, and he sacrificed it royally; for instance, in his work on roots he used 3000 beans. He insisted on things being done in a sound, cleanly manner, and especially inculcated the proper cultivation of experimental material, often reproving his pupils if they did not give light enough to their plants. He liked the practical details of cultivation, and would take pleasure, for instance, in showing his pupils the proper way of moistening earth for germinating beans; with the remark that this ought not to be done by a gardener, and adding "Das macht mir Spass" as a further reason for doing it himself. He preferred simple methods and broad results, and was essentially a man of round numbers. He did not deal in elaborate apparatus, and had indeed a somewhat unreasonable dislike for "Sogenannte Genauigkeit." But this was rather the dislike of unnecessary exactness, or of exactness misplaced—a valuable point of view in an experimentalist. He had, however, a liking for mechanism, as his invention of the recording auxanometer and of the klinostat shows.

As a lecturer he was admirable, and illustrated his words on the blackboard with evident pleasure and in the most life-like of sketches.

His papers have been collected in two volumes, published in 1892-3, many of the researches having appeared in his celebrated "Arbeiten," three well-known volumes, in which it was the highest ambition of his pupils to obtain a place.

The main point that strikes one about his work is that his was pure rather than applied physiology; he cared for the behaviour of a plant as he cared for a machine, not in relation to its environment. He was essentially not a biologist in the modern sense, though, as a matter of fact, he was an evolutionist.

His work may be divided, as he has himself classified it, into the physiology of nutrition and that of movement. In both these departments he laboured incessantly, and made numerous important discoveries; yet, in spite of what he added by his admirable researches, it seems to me that he was even more remarkable for his power of strengthening and marshalling a subject, and of placing it before the world with a vigour and clearness that ensured its acceptance.

Thus, in regard to nutrition, he established, by the most brilliant of his researches, the connection between carbon-assimilation and the existence of starch in the chloroplasts; yet his fame seems to me to rest with even greater certainty on the fact that he saw more clearly than any modern botanist the overwhelming importance of a just view of assimilation, and that he had the intellectual force needed to drive it into the minds of a generation of botanists.

In the same way he marshalled, remodelled and largely added to our knowledge of growth and growth-curvatures, and set forth his results with a style and force that were irresistible. But the conception of stimulus and reaction, now the central principle of plant—as of animal—physiology, only came to him imperfectly, as it seems to me. His use of the word *anisotropic* for organs behaving differently in relation to the same cause, implies a certain want of perception of the heart of the matter. The word is not really wanted, since the conception of irritability postulates what he called anisotropy. The stimulus is but a sign-post; the needs of the plant in relation to its environment necessitate that different organs shall be guided by the stimulus in opposite directions.

In spite of the strength and clearness of his way of thinking, there was in him a vein of something like mysticism, as, for instance, in his conception of a radial organ as corresponding to a dorsiventral organ rolled up like a scroll; or in his assumption of an invisible dorsiventrality in certain plagiotropic organs.

Again, there is in his views what strikes some of us as almost mediæval. For instance, his idea of the root-forming and shoot-forming material flowing in opposite directions, and thus accounting for the behaviour of cuttings. The same may be said of his views on etiolation, although in these days of the thyroid treatment of myxœdema it is rash to deny the feasibility of any explanation founded on the special nutrient value of definite substances. But it is juster to put aside these considerations, and in a broader spirit to remember only the masterly way in which, in his "Lectures" (1882), he developed the classification of organs into "root" and "shoot" into a system of physiological morphology, *i.e.* into a morphology which goes beyond phylogeny into the region of adaptation.

I have thought it right to speak plainly about Sachs' work, for I am assured that it contains so much of enduring value that it deserves the truth; and I willingly allow that in the points in which my estimate of this great man is less favourable than some of my contemporaries, I may be misled by that blindness of which I have already spoken.

In his later years his life was overshadowed by broken health, and his nature—sensitive and self-centred—was never compatible with a serene or happy life. Those who came under his influence must be glad to forget the less happy side of the picture, and remember with gratitude how much they owe to Sachs.

FRANCIS DARWIN.

PROFESSOR R. FRESENIUS.

CARL REMIGIUS FRESENIUS, whose death occurred last week, was born at Frankfurt-on-Main on December 28, 1818. After a preliminary training at a pharmacy in that town, he devoted himself to the study of natural science, more especially of chemistry and botany. In 1840 he entered the University of Bonn, but a year later went to Giessen, where Liebig chose him as assistant in his laboratory. He graduated at Giessen in 1843. In 1845 he was called to the professorship of chemistry, physics, and technology at the Agricultural Institute at Wiesbaden, with which he has since been identified. The chemical laboratory at Wiesbaden, founded, owing to his exertions, in 1848 by the Government of the Duchy of Nassau, has since been much enlarged, a school of pharmacy being added in 1862, and a research laboratory for agricultural chemistry in 1868. The direction of the latter was taken over by his son, Dr. Henry Fresenius, in 1881. Fresenius received the title of Geheim Rath of the Duchy of Nassau in 1855. His best-known works are his "Qualitative Analysis" (first published in 1841) and his "Quantitative Analysis" (published in 1846); both have passed through very numerous editions, and have been translated into almost every European language. His numerous original memoirs (there are 162 titles in the Royal Society's Catalogue between the years 1842 and 1883) deal almost exclusively with analytical chemistry. One of his earliest papers (1843) deals with the composition of a mineral water from Java, and this was a subject to which he frequently returned. A series of papers on the mineral waters of Nassau (1864-68) are well known. Many of his later papers are published in the *Zeitschrift für Analytische Chemie*, which he founded in 1862, and which he continued to edit until his death.

T. E.

NOTES.

M. HATT has been elected a member of the Section de Géographie et Navigation of the Paris Academy of Sciences, in succession to the late M. d'Abbadie; and Prof. de Lapparent, professor of mineralogy, geology, and physical geography in the Paris École libre des hautes études, has been elected a member of the Academy, in succession to the late M. des Cloizeaux.

WE regret to announce the death, at sixty-seven years of age, of Prof. P. Schützenberger, professor of chemistry at the Collège de France, and member of the Paris Academy of Sciences.

M. MAURICE LÉVY AND M. LÉAUTE will represent the Paris Academy of Sciences at the inauguration of the statue of Perronet at Neuilly, on Sunday next, July 4.

THE eightieth annual meeting of the Société helvétique des sciences naturelles (the Swiss Association of Naturalists) will be held at Engelberg, in the pretty Alpine village of Engelberg (Obwalden), on September 12–15. The Committee has issued a very cordial letter of invitation, in which it is pointed out that though Engelberg does not offer the resources and pleasures of a large town, or exhibit such a solid testimony to scientific movement as is seen at Zürich, where the Association met last year, nevertheless the little village at the foot of snow-capped Titlis has attractions of its own, and the welcome which will be extended to the members will be a very hearty one. The meeting will open with a reception at five o'clock in the evening of Sunday, September 12. On the following day there will be a general meeting, after which an excursion and a banquet will be the order of the day. On September 14 the sections will meet in the morning, but the afternoon and evening will be devoted to lighter pleasures. The second general meeting will take place on September 15, and the session will be closed on the same day. The railway and steamboat companies offer special facilities to members of the Association, and the charges at hotels will be reduced. The hearty invitation of the Committee, and the place of meeting (in one of the most beautiful valleys of the Alps), will doubtless attract many men of science to go with friends or families to Engelberg next September. It is hoped that those who propose to attend the meeting will notify their intention before the end of July. Letters should be addressed to the President of the Annual Committee, Herr E. Etlin, Arzt, Sarnen, Obwalden.

THE Albert Medal for the present year has been awarded, with the approval of H.R.H. the Prince of Wales, the President of the Society of Arts, to Mr. G. J. Symons, F.R.S., "for the services he has rendered to the United Kingdom by affording to engineers engaged in the water supply and the sewage of towns a trustworthy basis for their work, by establishing and carrying on, during nearly forty years, systematic observations (now at over 3000 stations) of the rainfall of the British Isles, and by recording, tabulating, and graphically indicating the results of these observations in the annual volumes published by himself."

THE annual meeting of the American Microscopical Society will be held at Toledo, Ohio, on August 5–7, under the presidency of Prof. E. W. Claypole.

IN the House of Lords on Tuesday, Lord Hobhouse moved the second reading of the Sunday Bill. The object of the Bill was to amend the Lord's Day Act of 1781, which is now being vexatiously used to repress attempts to improve the rational use of Sunday by means of lectures and musical performances. After discussion, the second reading was rejected by 50 votes to 33.

A PUBLIC meeting will be held in the Botanical Theatre of University College, Gower Street, to-morrow at 4 p.m., to inaugurate the personal memorial to the late Sir John Pender. Mr. Onslow Ford's bust of Sir John Pender will be on view, and a cheque for 5000*l.*, to endow the electrical laboratory of University College, will be handed over to the Trustees. The gift will be acknowledged by Lord Reay on behalf of the College. The Marquis of Tweeddale will preside, and Lord Kelvin is expected to be present and speak.

A COMMISSION, consisting of Prof. D. T. McDougal, of the State University of Minnesota, and Prof. Campbell, has lately visited Jamaica and other of the West Indian Islands, to select a site for an international botanical laboratory in the tropics. American botanists have long been considering the advisability and expediency of the establishment of such an institution, which, if it is founded, will be of great value as a permanent research laboratory.

THE New York Zoological Society is making special efforts to increase its membership and obtain subscriptions and endowments for the Zoological Gardens, to be established in South Bronx Park (see vol. lv. p. 613). The Society requires 250,000 dollars for the erection of animal buildings, aviaries, and other enclosures, and for the purchase of a series of mammals, birds, and reptiles with which to fill them. The sum of 100,000 dollars is urgently required, and should be obtained before August 1, as that amount must be pledged before any work on the proposed Zoological Park can begin. There ought not to be any difficulty in obtaining this amount if the rich citizens of the largest and wealthiest city in America have any public spirit.

AT Shoreditch, on Monday, Lord Kelvin opened a central electric station, in which the motive power is steam produced by a destructor which is to be fed with household refuse as fuel. From the *Times* we learn that there are twelve destructor cells, each having a grate area of twenty-five square feet, and heating six water-tube boilers working at a pressure of 200 pounds to the square inch. The chimney is 150 feet high and 7 feet in internal diameter at the top, and, in addition, there are three electrically-driven fans, which each deliver 8000 cubic feet of air a minute with a maximum ash-pit pressure of three inches of water. An interesting feature is the employment of Mr. Druitt Halpin's system of feed thermal storage. As it is necessary to keep the destructors burning continuously, steam is generated during all the twenty-four hours. But as power is required on a large scale during only a portion of that time, in order to reduce waste a plan of heat storage has been introduced, by which, during the day, steam is mixed in a vessel with cold water in such proportions that at evening the cylinder is full of water at the temperature and pressure of the steam required by the engines. The boilers are fed with this heated water, and are said to be enabled in consequence to produce one-third more steam than they would if working with water direct from the mains. As to the amount of refuse consumed, it is expected that the most efficient rate will be between eight and twelve tons a day. The electrical plant at present consists of three generators working at 1100 volts, and three low-tension dynamos at 165 volts. All are driven by Willans' three-crank engines, coupled direct. Orders have already been received to nearly the full capacity of the present plant. In declaring the undertaking ready for public use, Lord Kelvin said that it was worthy of the Victorian era as an example of the combination of scientific forethought, mechanical skill, and courage, which had nothing of gambling in it, but simply brought into practice recognised engineering possibilities. Dust destructors have been tried for some years in order to get quit

of refuse at a lower cost than is required for spreading it on the ground or carrying it out to sea, but little has been done in the way of using the heat of these dust-crematories for raising steam. Shoreditch is the pioneer vestry in this respect. But what has been done is only the small beginning of what will be a much greater thing, for all dust refuse will soon be used in the same way.

THE firing at Portsmouth on Saturday, on the occasion of the naval review, was distinctly heard at Hungerford, Wilts, a distance of forty-five miles, as the crow flies, and also at Great Malvern. It would be interesting to know whether the salutes were heard at greater distances than these.

IN accordance with the will of the late Prof. E. D. Cope, his collection of fossils is to be sold, and the proceeds devoted to establishing a chair of Palæontology in the Philadelphia Academy of Sciences, with which his name was so closely connected. The appointment to the chair must be approved by the National Academy, the duty being chiefly that of original research.

IT may interest some of our readers to know that the following are among the portraits recently acquired by the Trustees of the National Portrait Gallery:—Sir Francis Ronalds (1788–1873), inventor of the first working electric telegraph. A small plaster bust of Richard Jefferies (1848–1887), naturalist and author. A painting of Constantine Phipps, Lord Mulgrave, R.N. (1744–1792), represented in the Arctic regions while commander of H.M.S. *Racehorse* in 1773 on a voyage to the North Pole. Sir Joseph Williamson, P.R.S. (1630–1701), Secretary of State in 1674, and second President of the Royal Society.

A THUNDER-STORM of extraordinary violence passed over London on Thursday last, and did an immense amount of damage in Essex, every kind of crop over an area of about a hundred square miles being ruined. A description of the storm will be found in our correspondence columns. Hailstones of unusually large size fell during the thunder-storm. Mr. F. E. Allhusen, writing from Harrow-on-the-Hill, sends us a description of hailstones which fell there at about 1.50 p.m. The hail continued for about twenty minutes, and was followed by heavy rain. Referring to a number of hailstones picked up and examined within five minutes of their fall, Mr. Allhusen says:—"The majority were roughly spherical in shape, and had an opaque nucleus about the size of a pea. Round this there was a layer of clear ice, in several distinct concentric layers. The ice was honeycombed with small air-bubbles, arranged radially; many of these air-bubbles were much elongated. The general appearance of the hailstones was rough, and somewhat similar to that of the edible part of a walnut. . . . Twelve fairly large stones were weighed; they turned the scale at two ounces."

MR. J. A. MCMICHAEL, Head-master of the Technical Day School, Chester, informs us that on Sunday evening, June 20, at 7.45, he saw a distinct solar halo. The angle subtended by its radius was roughly estimated at 25°. No second halo was visible. The colours were easily seen, the red being inside. Mr. McMichael thinks the appearance of such a phenomenon four days before Midsummer Day is very remarkable, and would like to know if any of our readers could give similar instances.

IT is stated in *Science* that a Bill has been introduced in the Minnesota Legislature providing for the appointment of expert witnesses, and that a similar Bill has been prepared to be presented to the New York Legislature. The object of the Bill is to provide a list of experts from whom witnesses are to be selected by the Court and paid by the State. The following remark of our Transatlantic contemporary will find many supporters:—"The employment of expert witnesses by the counsel for the prosecution or defence has been unfortunate both for the Courts and for science. It would certainly be desirable to devise a plan by which the expert witness should be in the position of a judge rather than that of a paid attorney."

THE number and variety of scientific exploring expeditions in America this summer is surprising. The latest announcement is that Prof. Wm. Libbey, jun., of Princeton University, will in a few days lead a party of six explorers to Albuquerque, New Mexico, to explore a mesa or sandstone tableland near there. The outcroppings of red sandstone project from the face of the walls, rendering it almost inaccessible. Cliff dwellings have been seen along the edges, and fragments of pottery at the base indicate occupancy by a pre-historic race; but the tableland has never been scaled in historic times, so far as known. Prof. Libbey intends to throw a line over this tableland, which is several acres in extent on top, by means of tandem kites; or, in case the wind should be too light, by means of a mortar which will fire a life line across the top. Larger lines will be drawn over, and the ascent made in a boatswain's chair.—Mr. Jesse D. Grant, son of General Grant, is sending an expedition to explore the islands in the Gulf of California, north of 29°, which parallel intersects Tiburon Island, inhabited by the fierce and little-known cannibal Ceris Indians.

TWO exploring expeditions are now on their way to Mount St. Elias—one from the United States, the other from Italy. The object of the American expedition is to make a survey of the region, and settle the boundary dispute with Great Britain. The 141st meridian of west longitude is the boundary line, and the summit of the mountain was found by the commission appointed in 1891 to be approximately 60° 17′ 51″ N. and 140° 55′ 30″ W. It is said to be thirty-three miles inland, whereas the jurisdiction of the United States extends ten marine leagues or 34½ miles; thus, it would seem, taking in the summit. Mr. E. B. Tatham, of the United States Coast Survey, will conduct this work. The party will be led by Mr. Henry G. Bryant, of Philadelphia, who explored the great falls of Labrador in 1891, and was leader of the Peary Auxiliary Expedition in 1894. Mr. Samuel J. Enterkin, who goes with the party, was with the Peary party on its journey to the ice cap in March 1894.

THE Italian expedition to Mount St. Elias is led by Prince Luigi Amadio of Savoy, who is accompanied by four aides, Chevaliers M. Cagni, Francesco Gonella, Vittoria Sella, and Dr. Filippo De Filippi. After the ascent, this party will attempt to climb Logan's Peak. Mount St. Elias is over 18,000 feet high, and was for a long time considered the highest mountain on the American continent. The summit has never been reached, though several attempts have been made, notably in 1891, when the surveying party reached the height of 14,500 feet. The reason of the failure of former parties is said to be that the approach was made on the south side, where there is a heavy fall of snow and tremendous avalanches, glaciers, precipices, and chasms. The northerly side, from which the ascent will now be attempted, is more approachable, owing to a long ridge of mountains.

WE learn with regret that Mr. W. J. C. Millar has been compelled by ill-health to resign the post of mathematical editor of the *Educational Times*, which he has held for the past forty years. Mr. Millar's labours have been purely honorary, and his collections of problems and mathematical riddles have inspired and directed the early efforts of many mathematicians of the highest eminence, including such names as Clifford, Cockle, Cayley, and Sylvester. It is now

proposed to present Mr. Millar with a testimonial in recognition of his services, and towards this purpose 40*l*. has been already received. The Rev. Robert Harley, F.R.S., of "Rosslyn," Westbourne Road, Forest Hill, S.E., has kindly undertaken to receive contributions, which it is hoped will be "*numerous* rather than *large*," the object being to show Mr. Millar how widely his work has been appreciated.

IT is somewhat remarkable that, although the conception of the centre of gravity was evidently known to Archimedes, those of his writings which have been handed down to us nowhere contain either a definition or a proof of the existence of that point. This gap has been attributed to his having treated the subject in a lost work on balances, quoted by Pappus. An important contribution to our historical information has now been made by Dr. Giovanni Vailati (*Atti della R. Accademia delle Scienze di Torino*, xxxii.), who has found fresh material in an Arabic translation of an unknown work by Hero, of Alexandria, in the library of Leyden. This work was brought over in the seventeenth century by Golius, then Professor of Mathematics and of Oriental Languages in the University of Leyden, and attention has recently been directed to it by Carra de Vaux. In it Hero makes numerous references to Archimedes' lost manuscript, from which Dr. Vailati has been enabled to build up, with a fair degree of certainty, the arguments by which Archimedes proved the existence of the centre of gravity.

DR. F. CAMPANILE and Dr. E. Stromei (*Rendiconti dell' Accademia delle Scienze di Napoli*, iii. 4) describe some further experiments on the phenomena of phosphorescence observed by them in Crookes and Geissler tubes. This phenomenon consists in the production of phosphorescence and Röntgen rays on the walls of a Geissler tube opposite two plates of tinfoil which were attached to a Ruhmkorff coil or to an electrostatic machine, connected with a spinterometer.—A somewhat different line of investigation has been taken up by Prof. Battelli (*Nuovo Cimento*, v., March 1897), who has studied the variations in the photographic action both inside and outside a vacuum tube, and their dependency on the form and dimensions of the tube, the form of the electrodes, the intensity of the current, and the degree of rarefaction.—In a subsequent number of the *Nuovo Cimento*, Signor P. G. Melani discusses the influence of magnetism on discharges in vacuum tubes, and describes a number of experiments carried out in Prof. Battelli's laboratory at Pisa.

ALONG with a fine series of reptiles lately presented to the Zoological Society's collections, Mr. F. W. Urich has sent from Trinidad a nest of the "Sauba" or Parasol Ant, *Œcodoma cephalotes*, the extraordinary habits of which are well known to naturalists. The colony has been placed in a glass case in the Zoological Society's Insect House, where the workers may be seen every day cutting out bits of leaves from a plant that has been provided for their use, and conveying them into their subterranean dwellings.

A NEW Tortoise House, placed near the Reptile House, has just been completed in the Zoological Society's Gardens, and the various specimens of the *Testudinata* will shortly be removed there from their present quarters on the further side of the canal, so that the whole of the reptile collection will be together. The most remarkable of the tortoises are two fine adult specimens of the Giant Tortoise of the Aldabra Islands in the Indian Ocean, which were presented to the Society by Rear-Admiral Kennedy in 1894. There are also three other examples of the same, or of a nearly-allied species, which have been recently received "on deposit" from the Hon. Walter Rothschild.

AUTHORITIES on Indian birds seem to be unanimous in the opinion that the common little Cotton-Teal or Goose-Teal, *Nettopus coromandelianus*, is unable to stand and walk like other ducks, but invariably flutters along in a strange scuffling manner, like a wounded bird. At a recent meeting of the Asiatic Society of Bengal, Mr. F. Finn gave reasons for doubting the accuracy of this statement. He has had many opportunities of observing Cotton-Teal in confinement, and after watching the gait and movements of numerous specimens, he asserts that the inability to walk, attributed to the species by many observers, is not in reality natural to it, but merely the result of fright, weakness, or injury.

Science Gossip for June reproduces from the *Journal of Malacology* some very interesting sciagraphs of shells by Mr. W. M. Webb, which seem to show that the Röntgen rays are of practical value for studying their interior structure. In a paper read before the Natural History Society of Buda-Pesth, Dr. J. Istvánffy states that, in the case of living plants, the Röntgen rays penetrate only the woody tissue. In a leaf of *Camellia* exposed to them, the veins appeared white. All other tissues, whether containing chlorophyll or not, are impenetrable to them.

WE are glad to see that the *Gleaner*, of Kingston, Jamaica, is urging the appointment of a geologist to examine the new sections which will be exposed during the construction of a new road now being made over the mountains. The palæontology of Jamaica has been very little studied. There is a very poor collection of fossils in the local museum. It is a little better with mineralogy, but so slight has been the interest taken in all branches of geological science that there are both fossils and minerals from local sources in the museum, about which there is absolutely nothing known; all trace of their origin and other circumstances having been lost. What is really wanted is a Government geologist, to devote himself exclusively to geological observations; and if the appointment of such an officer cannot be entertained at present, the least that should be done is to commission a geologist to map the sections which the road-builders will expose, and save whatever vestiges of vanished ages may be obtained. The facts thus accumulated would be of the greatest value when a survey of the country comes to be made.

MESSRS. GINN AND CO. will shortly publish the first number of the *Zoological Bulletin*, a companion serial to the *Journal of Morphology*, and designed for shorter contributions in animal morphology and general biology. The *Bulletin* will differ from its German prototypes chiefly in excluding, at least for the present, bibliographical lists. Its contents will consist wholly of scientific communications. The editorial work will be directed by Profs. C. O. Whitman and W. M. Wheeler.

IN connection with the excursion of the Geologists' Association to Edinburgh, from Monday, July 26, to Saturday, July 31, the four following papers will be read at a meeting of the Association at University College, London, to-morrow, July 2, at 8 o'clock:—"Outline of the Geological History of the Rocks around Edinburgh," by Mr. J. G. Goodchild; "Excursions from Bathgate to Linlithgow, and from St. Monans to Elie," by Prof. James Geikie, F.R.S.; "Fish Remains in the Abden Bone-bed," by Dr. R. H. Traquair, F.R.S.; "The Stirling District," by Mr. H. W. Monckton.

THE Report of the Government Observatory, Colába, Bombay, for the year ended March 31 last, presents two special points of interest: (1) The introduction of a Dines' pressure tube anemometer, the vane of which is erected about 3 feet above the cups of the Robinson anemometer, and about 6 feet from it. A comparison of the results of the two instruments during the short period of the erection of the new anemometer shows that the average velocity recorded by the old instrument is 42 per cent. more than the average velocity given by the

Dines' anemometer, confirming the results of other observers that the factor 3 (the ratio of the speed of the wind to that of the cups) is too great. (2) The Director is able to report a clean bill of health in his little colony (numbering altogether about 100 persons, including servants and their families) during the plague epidemic. This satisfactory state is attributed to additional ventilation, by removal of tiles, &c., to fumigation twice a week by carbolic acid, to inoculation of every man, woman, and child with Dr. Haffkine's prophylactic serum, and to the daily inspection of the quarters and inmates.

THE additions to the Zoological Society's Gardens during the past week include a Servaline Cat (*Felis servalina*) from East Africa, presented by the Rev. Ernest Millar; a Vulpine Phalanger (*Trichosurus vulpecula*) from Australia, presented by Mr. M. A. Murray; a Common Squirrel (*Sciurus vulgaris*), British, presented by Lady Acland Hood; two Bateleur Eagles (*Helotarsus ecaudatus*), two Common Herons (*Ardea cinerea*) from East Africa, presented by Mr. Chas. Palmer; a Red-crested Cardinal (*Paroaria cucullata*) from South America, presented by Miss Edith M. Kenyon Welch; a Grey Monitor (*Varanus griseus*) from Egypt, presented by Dixon Bey; two Natal Pythons (*Python sebæ*, var.) from Natal, presented by the Hon. R. Carnegie; an Orang-outang (*Simia satyrus*, ♂) from Sumatra, deposited; two King Penguins (*Aptenodytes pennanti*) from the Antarctic Seas, purchased; a Burchell's Zebra (*Equus burchelli*, ♀), a Japanese Deer (*Cervus sika*, ♀), two Glossy Ibises (*Plegadis falcinellus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

PERSONAL EQUATIONS IN TRANSIT OBSERVATIONS.—In the reduction of transit observations the question of personal equation is an important factor in the accuracy of the final star places, and it is on this account that investigations are always being pursued to determine the values of these equations for each meridian observer. A communication of importance in this respect appears in the *Monthly Notices* for May, by Prof. Truman Safford, who treats of the various forms of personal equation in transit observations which arise from the non-observance of the exact time of transit due to personality, magnitude of the star observed, and the apparent velocity and direction of movement. In his investigation Prof. Safford concludes that since the year 1795 most eye and ear observers anticipate the true time of transits, taking the average observed as a standard. At Greenwich, since 1885, the great majority of observers by the eye and ear method anticipate the time of their own chronographic transits, while the average chronographic observer registers transits after the time of their occurrence by an amount not greatly different from that which is required to register an impression on the senses. The personal error arising from the rate of movement of the star, or as it is termed the polar equation, amounts sometimes to a very considerable quantity, and several values are given in the paper showing the importance of a strict elimination of this variable. Dealing with faint stars an observer using the chronographic method registers its time of transit later than that when a more bright one is taken, while with the eye and ear method the time of transit is generally somewhat earlier. The change in direction of motion of stars due to their being observed sometimes north and sometimes south of the zenith, gives rise to a further personal equation discovered by Dr. Gill, but which is found generally very small. The investigation shows that the general theory thrown out by Bessel is thus confirmed, and Prof. Safford points out that the same is true with regard to Wundt's explanation of the eye and ear process from a psychological point of view.

PARIS OBSERVATORY REPORT.—In his annual report for the year 1896, M. Lœwy, after a brief reference to the loss the observatory sustained in the death of M. Tisserand, sums up the work of the past twelve months. Among some of the chief points to which reference is made, may be mentioned the two astronomical congresses that have been held at the Observatory, and the work connected with the great enterprise of the photographic chart of the heavens. Many of the difficulties connected with the latter have for the great part been overcome, but there still remain one or two important questions which have been left over for another meeting. M. Bigourdan's work on the determination of the accurate position of the nebulæ between declination 90° and −30° has made great progress, and it is expected that it will take him three years more to complete the whole region under survey. The work on the photographic atlas on the moon has been successfully continued, and besides the issue of the first portion of the atlas during the past year, a second one will be published in the present one. The report further gives a brief account of M. Deslandres' work on the motions of stars in the line of sight, and the results of the expedition to Japan to observe the solar eclipse of August last. The work done in other departments of the observatory during last year, such as the Bureau des Calculs, Service Meridien, &c., is also briefly described.

BELGIAN TIME-RECKONING.—Since the beginning of May, the hours in Belgium have been reckoned from 0 to 24, noon being represented by 12, and midnight by 0 or 24, according to circumstances. In the case of a train starting exactly at midnight, it is said to leave at 0 hour; and one arriving exactly at midnight is considered due at 24 hours, or, as we should say, at 24 o'clock. We learn from the *Journal* of the Society of Arts that on the time-tables the times between midnight and 1 a.m. are indicated by a zero, followed by a point and the letter H, the latter followed in turn by the number of minutes. The dials of existing clocks at railway stations are completed by the figures 13, 14, 15, &c., to 24, added below the existing figures of 1, 2, 3, &c., to 12. This change, which should have come into force with the new year, was deferred for three months, on account of the administrative difficulties which it involved, and also in the hope that the Greenwich meridian, now adopted in Belgium, might also be accepted by France at the same time, urgency having been voted for a measure to that effect by the Chamber of Deputies.

A NEW CLASSIFICATION OF STELLAR SPECTRA.[1]

MANY of the recent advances in our knowledge of the constitution of the stars are traceable to Prof. Pickering's revival of Fraunhofer's mode of investigating stellar spectra. The endowment of this research by Mrs. Draper as a memorial to her husband, Dr. Henry Draper, has enabled Prof. Pickering to apply this method in two principal directions. First, a series of photographs was taken on a small scale to indicate the chief characteristics of the spectra of a very great number of stars; second, in the case of the brighter stars, another series was taken with greater dispersion with the view of facilitating an inquiry into the more minute features of each type of spectrum. The results of the first investigation are comprised in the well-known "Draper Catalogue," giving particulars of the spectra of over 10,000 stars (NATURE, vol. xlv. p. 427), and the research has now been advanced another stage by the publication of the results obtained along the second line of inquiry.

The new series of photographs has been taken with one to four objective prisms of 15° each in conjunction with the 11-inch Draper telescope of 153 inches focal length.

When four prisms were employed, the spectra were 8 centimetres long from H_β to H_ϵ, and with one prism 2 centimetres. Since only the brighter spectra could be photographed with the highest dispersion, some of the more typical of these were also photographed with one and two prisms in order to give a proper term of comparison with the spectra of the fainter stars. In all, 4800 photographs of the spectra of 681 of the brighter stars north of declination −30° are included in the present discussion. By the use of plates stained with erythrosin the spectra of several stars have been photographed in the green and yellow.

As in all previous work involving considerable numbers of stellar spectra, it has been found that the spectra can be classified in large groups, between which there are intermediate varieties. "Large numbers of almost identical spectra are found, even when several hundred lines appear in each." The description of the spectra accordingly takes the form of an account of typical stars in the scheme of classification adopted, accompanied by tables of the lines which characterise the larger groups. No

[1] Spectra of bright stars, photographed with the 11-inch Draper telescope as a part of the Henry Draper Memorial, and discussed by Antonia C. Maury, under the direction of Edward C. Pickering. (*Annals of Harvard College Observatory*, vol. xxviii. part 1, 1897.)

attempt has apparently been made to assign chemical origins to the various lines, so that the endeavour to arrive at a natural and satisfactory system of classification may be regarded as the most important part of the discussion.

The classification of stars has another object besides that of the mere grouping together of those which have similar spectra. It is generally believed that the various types of spectra represent different stages of stellar evolution, but there are divergences of opinion as to the exact order in which the various types should follow each other. Dr. Vogel still holds, with some slight modifications, to the classification which he suggested in 1874, and believes that all the stars can be arranged along a descending line of temperature. Sir Norman Lockyer, who has adopted the same method of work as Prof. Pickering, and has also obtained large-scale photographs of stellar spectra, finds evidence that there are some stars which are getting hotter while others are becoming cooler, so that two series of spectra can be recognised.

For the Draper Catalogue a somewhat arbitrary and provisional classification was adopted, but this has not been found sufficient to meet the requirements of the more detailed results which are now available.

Among the stars with line spectra, as previous researches have shown, there are a few sets of lines which occur with various relative intensities in different stars, each set in some degree varying bodily, and the new classification is based chiefly upon the distribution of these sets. As will appear later, the classification adopted by Miss Maury also takes account of the appearance, as well as of the positions of spectral lines, and every care has been taken to eliminate instrumental sources of error.

Four distinct sets of lines are distinguished. The first includes the lines of hydrogen and calcium, and the remainder are thus described:—

"Another class of lines frequently mentioned comprises those which are characteristic of the solar spectrum, excluding the lines of hydrogen and calcium. They are called 'solar' lines, except when referring to lines not contained in the solar spectrum, in which case they are called metallic lines."

"A third class of lines includes those known as 'Orion lines,' from the fact that they are conspicuous in the spectra of many stars belonging to the constellation Orion. . . .

"Certain stars, such as α Cygni and δ Canis Majoris, have spectra in which the majority of the lines, though probably identical in position with lines belonging to the solar spectrum, differ greatly in intensity, while others apparently are not represented in the solar spectrum. The characteristic lines of such stars should perhaps be regarded as forming a class distinct from those already described."

Bearing in mind these different classes of lines, the new system of classification can readily be understood. Excluding "composite" spectra and bright line stars, "the stars were arranged in an apparently progressive series, which in the present case was made to include twenty-two groups. . . . But it also appeared that a single series was inadequate to represent the peculiarities which presented themselves in certain cases, and that it would be more satisfactory to assume the existence of collateral series."

Three lines of progression are recognised in the earlier stages, and are called "divisions." Stars of division *a* are characterised by lines having the appearance with which we are familiar in the solar spectrum; that is, they are fine and sharp, if hydrogen and calcium be excluded. Those of division *b* are uniformly hazy, as in α Aquilæ, but otherwise present no notable differences in relative intensity from corresponding lines which are sharp in division *a*, so that "there appears to be no decided difference in the constitution of the stars belonging respectively to the two divisions." In division *c* the hydrogen lines are narrow and sharp and less intense than in the other divisions, while several lines, some of which do not correspond with solar lines, are of unusually great intensity; these are especially marked in α Cygni.

Groups and divisions alike proceed by very gradual stages in some parts of the series, and it has frequently been found difficult to assign some of the stars their proper places.

In consequence of the adoption of the term "group," which has been in use for the last ten years in connection with Sir Norman Lockyer's classification, some confusion may possibly occur, as similarly numbered groups include different stars. To avoid ambiguity, it will therefore be necessary, in the case of the first seven groups at least, to specify the system of classification in question. In what follows, the Draper groups will be distinguished by the addition of the letter D to the number where necessary.

Of the twenty-two groups, the first five include stars in which the Orion lines are especially marked; the sixth contains stars intermediate between this type and the first type of Secchi, to which belong the stars in the seventh to the eleventh groups inclusive. The twelfth group is intermediate between Secchi's first and second types, and the stars included in groups thirteen to sixteen are of Secchi's second type. Groups seventeen to twenty inclusive correspond to Secchi's third type, and groups twenty-one and twenty-two to the fourth and fifth types respectively. Besides these, two unnumbered groups are recognised, one containing composite spectra, apparently resolvable into two or more, and the other including stars of the Orion type which also show bright lines. Nebulæ find no place among the numbered groups, but reference is made to a former paper (*Ast. Nach.*, vol. 127, p. 1), in which it was suggested that the Wolf Rayet stars probably form a connecting link between the spectra of nebulæ and those of the Orion type.

It is not possible within the limits of this notice to indicate the full details of the twenty-two groups with their sub-divisions, but the general course of development which is suggested may be briefly stated.

In Group I. D, of which ι Orionis is a type, the hydrogen lines are comparatively faint, while the Orion lines are strong, and "solar" lines are absent. Passing to Secchi's first type, through Groups II. D to V. D, the Orion lines become fainter and less numerous until in the spectrum of Sirius (Group VII. D) all but two or three are wanting. Meanwhile solar lines have become numerous, and the hydrogen lines reach their maximum intensity. The transition to succeeding groups is very gradual, hydrogen lines thinning out and solar lines becoming stronger. Arriving at stars like Capella and the sun (Group XIV. D), the intensity of the hydrogen lines is little more than a tenth of that shown in Sirius, and they afterwards continue to decrease, but less rapidly, down to the third type stars (Groups XVII. D to XX. D), where they are inconspicuous. In the third-type stars banded absorption appears, and becomes more marked in each succeeding group, while the majority of the lines fade out in the later groups. An important feature of the series is the manifestation of extensive absorption in the later groups of second type stars and in those of the third type.

For the present, the series is regarded as ending with the spectra of the third type, stars following the twentieth group not being considered as having a place in the series exhibiting the gradual development of stellar spectra.

Spectra of division *c* are not found after the thirteenth group, and those of division *b* disappear still earlier, "so that the series tends to become more uniform as it progresses."

In connection with the new classification, it is remarked (p. 11) that "while it will be generally admitted that the series represents successive stages in stellar evolution, it may still be doubted whether the arrangement beginning with the Orion type, and here adopted, is in fact the natural order. It is strongly indicated, however, by the gradual falling off of the more refrangible rays in the successive groups, by the corresponding increase in the less refrangible rays, and by the occurrence of marked absorption at the close of the series. The comparative simplicity of the Orion spectra and the increasing complexity shown throughout the series, lends additional weight to the argument. Finally, the prevalence of the Orion type in great nebulous regions, as in Orion and the Pleiades, indicates very emphatically that stars of this type are in an early stage of development."

It will be seen that the supposed evolutionary series has been arrived at without reference to temperature considerations. Nevertheless, a gradual reduction of temperature as the series progresses is suggested by the diminishing intensity of the more refrangible rays, so that, in the main series at least, the order is in all probability one of gradually reducing temperature.

As already remarked, the stars of Secchi's fourth type have been omitted from the supposed evolutionary series of spectra, for the reason that the few lines photographed "have not yet been identified with those of other classes of stars, owing to the total dissimilarity of the spectra." This dissimilarity is stated to extend to the yellow part of the spectrum, and is difficult to comprehend in the light of the more recent results obtained by Dr. McClean, who has shown that the spectrum of 152 Schj. contains many lines which are apparently identical with lines in

the spectrum of α Orionis (*Monthly Notices*, vol. lvii. p. 8). The existence of carbon absorption in the solar spectrum, however, is of itself, as Lockyer long ago insisted, a sufficient connecting link between stars resembling the sun and stars in which carbon absorption is predominant. A classification which excludes these stars from the evolutionary series cannot, therefore, be regarded as final.

It is perhaps unfortunate that the new classification was adopted prior to the discovery of terrestrial sources of helium. Many of the "Orion" lines are now known to be due to this gas, but not all of them, so that these lines may be sub-divided into groups. In the preface to the volume Prof. Pickering remarks: "As the investigations were made several years ago, they could not take account of the recent discoveries respecting the spectrum of helium, which, if known at the time, might have had an important influence upon some of the conclusions. Such modifications could not now be introduced without practically rewriting the treatise, which is therefore published without change. A discussion of the relation of the spectra of stars of the Orion type to that of helium has, however, been made, and is contained in the supplementary notes."

The question of classification, however, is not the sole feature of interest possessed by the spectroscopic work at Harvard. Besides this, there are several tables which give the wavelengths of the lines depicted on the photographs, a general catalogue of the spectra, and copious remarks on the spectra of individual stars. In the case of the composite spectra it has been noted that in all but one, o Andromedæ, the spectrum of the earlier type was the fainter. The peculiarities of the spectrum of γ Cassiopeiæ, already recorded by Lockyer (NATURE, vol. li. p. 425), have been fully confirmed, and the additional fact observed that the entire region of the spectrum from λ 4154·7 to 3927·1 appears brighter than the rest of the spectrum, although the brightening is not homogeneous. The possible importance of this feature is suggested by its occurrence also in stars of the first two groups of the new classification.

The complex phenomena in the variable spectrum of β Lyræ are fully detailed, and the composite character of the dark line spectrum detected at Kensington by Sir Norman Lockyer receives independent confirmation. It is concluded that "the bright bands accompany a spectrum approximately of Group IV. D (*e.g.* γ Orionis), which oscillates periodically over one of Group VII. D, division c" (*e.g.* η Leonis), a result which agrees very closely with Lockyer's conclusion that the two dark line stars were not very unlike γ Orionis and β Orionis. It is pointed out that the supposition of a system of three bodies explains most of the spectral phenomena of β Lyræ, but not all of them, and the rapid and complex transformations require to be continuously followed before a complete explanation can be given.

While fully aware of the difficulty attending the satisfactory reproduction of stellar spectra, we think the value of the volume would have been greatly increased by some attempt to give copies of photographs of as many as possible of the typical stars. Without such reproductions the classification can scarcely be adopted by others taking up the work unless photographs of all the typical stars are first obtained. In spite of this drawback, the volume is a magnificent contribution to celestial spectroscopy, and will be of the greatest value to those pursuing similar investigations. Prof. Pickering and his assistants are to be congratulated upon the excellence of this additional contribution to the Henry Draper Memorial. A. FOWLER.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

MOST of the arrangements for the approaching meeting of the American Association for the Advancement of Science have now been made, and are announced in the preliminary circular of the local committee. The meeting will be held at Detroit, Michigan, August 9-14. All the meetings, both general and sectional, will be held in the Detroit Central High School.

The chairman of the local committee is General Russell A. Alger, Secretary of War of the United States. The committee contains a great number of distinguished names, including seven or eight presidents of colleges, and several governors, senators, and foreign ministers.

The first session of the American Association, on Monday morning, August 9, will be opened by Prof. Theodore Gill, senior vice-president, owing to the death of President Edward D. Cope. The President-elect, Prof. Wolcott Gibbs, will be introduced, and addresses of welcome will be made by Mayor Maybury and by the ex-Minister to Spain, Mr. Thomas W. Palmer, after which the sections will meet. The addresses by the several vice-presidents of the sections will be as follows:—Prof. Carl Barus, to the section of physics, on long range temperature and pressure variables in physics; by Prof. Wm. J. McGee, to the section of anthropology, on the science of humanity; and by Prof J. C. White, to the section of geology and geography, on the Pittsburg coal bed (the latter to be read in his absence at the Geological Congress at St. Petersburg); Prof. W. W. Beman, to the section of astronomy and mathematics, on a chapter in the history of mathematics; by Mr. Richard T. Colburn, to the section of social and economic science, on improvident civilisation; and by Prof. L. O. Howard (nominated to succeed the late Prof. G. Brown Goode), to the section of zoology, on a subject to be hereafter announced; Prof. W. P. Mason, to the section of chemistry, on sanitary chemistry; by Prof. George F. Atkinson, to the section of botany, on experimental morphology; and by Prof. John Galbraith, to the section of mechanical science and engineering, on applied mechanics.

A general session will be held on the evening of the opening day, and Prof. Theodore Gill will deliver, as the presidential address, a memorial of the life and work of the late president, Prof. Edward D. Cope, after which will follow a reception by the citizens of Detroit.

August 10-13 will be occupied as usual by section meetings, and to some extent by excursions of the sections. A new arrangement has been made by which the affiliated societies will occupy a portion of the time heretofore allotted to the sections; and these meetings will be open to members of the Association, as those of the several sections are to members of the affiliated societies. Only three societies meet this year in connection with the Association, namely, the Geological Society of America, the American Chemical Society, and the Society for the Promotion of Agricultural Science. These several societies meet on August 9-11. The Association of Economic Entomologists anticipates the others, holding its meetings on August 6 and 7. Of the other Societies usually affiliated with the Association, the American Mathematical Society will meet at Toronto on August 17-18; and the Society for the Promotion of Engineering Education on August 16-18.

The closing meeting of the Association will be held on the evening of August 13, followed by a reception.

There will be a general excursion by steamer to St. Claire Flats on August 14, the contemplated trip to Buffalo and Niagara Falls having been abandoned.

Attention is again called to the fact that members of foreign scientific associations of a national character are admitted without fee to the meetings of the American Association.

Matters relating to local arrangements, transportation, &c., are in the hands of the local secretary, Mr. John A. Russell, No. 401 Chamber of Commerce, Detroit, Mich. Hotel and boarding-house accommodation is arranged by Mr. Edward W. Pendleton, of the same address. Nominations to membership and letters relating to the general business of the Association should be sent to Miss C. A. Watson, assistant secretary, Salem, Mass., until August 3; after that date to the American Association, Detroit, Mich.

The circular repeats the announcement that after the close of the meeting it is expected that members of the American Association will go in a body to Toronto to join in welcoming the British Association to America. Special rates of fare will probably be secured for this purpose.

The several sections will issue preliminary circulars. The first to appear is that of the anthropological section, which states that Tuesday, August 10, will be devoted to folklore, to which the American Folklore Society has been invited. On Wednesday the report of the committee on the ethnography of the white race in America will be presented in the morning, to be followed by discussion; the subject of psychology will occupy the afternoon. Thursday forenoon will be devoted to the archæology and ethnology of Mexico and Central America; afternoon, to the United States. On Friday morning the report of the committee on anthropologic teaching will be received; and in the afternoon the subject for consideration will be somatology.

THE ANALYSIS OF PHONOGRAPH RECORDS.[1]

AFTER describing the general characters of waves, as regards pitch, amplitude, and form, Dr. McKendrick said :—

Thus we can now understand what is meant by a compound wave, and you will appreciate the statement that compound waves may be very complex in character. If you look at the curves showing the resultant waves, you will see that they represent, in a way, the character of the variations of pressure made on the drum-head. With simple pendular waves, the drum-head moves out and in with perfect regularity, like the movements of a pendulum. The physiological effect of such simple pendular vibrations is a sensation of a pure tone, such as you hear when I bow this tuning-fork. But if a compound wave falls on the drum-head, it is not so easy to follow with the imagination the variations of pressure. While these variations occur in regularly recurring intervals of time so as to give the sensation of the pitch of the fundamental tone, the movement may not be uniform on each side of the median line, indicating the position of repose of the drum-head, like the swing of a pendulum. Thus the drum-head may move in, owing to the increase of pressure, faster than it moves out, or the reverse; or it may move in a little distance, then return again to the starting-point and again move in, and it may return to the position of rest after one or more to-and-fro movements Again, it may be pushed in to the maximum distance, and remain in that position for a short time, and then return to the original place of repose. Thus the characters of the variations of pressure may vary to a remarkable degree—to a degree, with a very complex sound, that is to us almost inconceivable; but we may be sure that these variations of pressure will be faithfully followed by the drum-head, and communicated by it to the deeper ear. When a compound wave thus falls on the ear, the result is a sensation of sound of a certain quality, or timbre, or clang, and we say that we hear the sound of various musical instruments, as in a brass band or an orchestra, or the sound of a particular instrument, a trombone, a flute, a harp, a clarionet, or the sound of a well-known voice that we can distinguish from all others.

He then described the attempts to record graphically the vibrations of bodies emitting sound from the time of Thomas Young down to 1874-75, when the phonograph was invented. In 1878, Fleeming Jenkin and Ewing succeeded in obtaining tracings of the records of vowel sounds on the tinfoil phonograph, and the curves were submitted to harmonic analysis. Since that time, the marks on the tinfoil of the first phonograph have been scrutinised by Grutzner, Mayer, Graham Bell, Preece, and Lahr. The imperfections of the tinfoil phonograph made progress impossible for ten years (from 1878 to 1888), during which time, however, Edison, Graham Bell, and others were engaged in working out the mechanical details of the wax-cylinder phonograph. The subject was then taken up by Hermann, and he succeeded in obtaining photographs of the vibrations of the vowel sounds, a beam of light reflected from a small mirror attached to the vibrating disc of the phonograph being allowed to fall on a sensitive plate while the phonograph was slowly travelling. The curves thus obtained were very beautiful. In 1891, Boeke, in a laborious microscopical research, measured the transverse diameters of the depressions on the wax cylinder at different depths, and from these measurements calculated the depths of the curves. He then reconstructed the curves on a large scale, and he also has been busily engaged in the analysis of vowel curves.

Recently also Pipping has traced and analysed the curves obtained by a kind of phonautograph constructed on the type of the drum-head of the ear, and R. J. Lloyd has written two valuable papers on the interpretation of the tracings obtained by Pipping and by Hermann.

Dr. McKendrick exhibited one of the first phonographs made in this country. It was constructed by the late Prof. Fleeming Jenkin in 1876. It represents the instrument in its simplest form. You observe how the drum travels from side to side as in the phonautograph. The drum has a deep spiral groove, the thread of which corresponds to that of the spindle on which the drum rotates, and it is covered with thin, soft tinfoil. The membrane has fixed firmly to its centre a stout little marker having a chisel-shaped edge. When sound waves fall on the membrane it vibrates, and as the drum is rotated, the edge of the needle pushes in the tinfoil into the spiral groove, and it makes a series of indentations corresponding to the variations of pressures produced by the sound waves. When the sound is reproduced, we run the point of the needle over these indentations by turning the drum, and the varying pressures on the needle point caused by the indentations act on the membrane, and reproduce the sound. Thus this simple mechanism records the *number* of vibrations, corresponding to pitch, the relative *amplitude* of the vibrations, corresponding to intensity or loudness, and the *form* of the vibrations which has reference to the quality of the sound.

Since this remarkable invention first appeared, the phonograph has been improved so as to make it now a valuable scientific instrument. Many are too apt to think of it as an amusing toy, or as an apparatus that will serve the practical purpose of a shorthand writer. It is both amusing and practical, but it is much more. It is now a scientific instrument worthy of a place in physical and physiological laboratories beside other instruments of scientific research, and those employed for demonstration in teaching. It merits this position because it makes it possible to study some of the phenomena of sound in a manner otherwise unattainable.

Since 1877 the phonograph has been immensely improved, and we now have it in the form that you see before you. The machine used in this country is so geared that the wax cylinder, 6⅝ inches in circumference, makes two revolutions in one second, while the spiral grooves described on the cylinder are 1/200 inch apart. A spiral line about 136 yards in length may be described on the cylinder, and the recording or reproducing point travels over this distance in about six minutes.

I have also used the American model, now also before you, which resembles in all essential particulars the one I have just described, except that the grooves are 1/100 inch apart, instead of 1/200 inch.

The mechanism by which the glass disc or diaphragm communicates its movement is shown by means of the large model now before you. When sound waves fall on the glass disc, the latter is subjected to variations of pressure, as I have already explained. From the centre of the glass disc there comes a rod which passes to the end of a lever, and to this lever a counterpoise is attached. The end of the lever carries a sapphire point which, like a gouge, cuts a spiral groove on the surface of the wax cylinder. When there is increased pressure on the disc, the inclination of the edge of the gouge is directed downwards at such an angle with the surface of the wax cylinder as to cut a groove of a certain depth; but when the pressure becomes less, the angle is changed, the gouge cuts more in a horizontal direction, and the groove ploughed out is not so deep. Consequently as with each vibration of sound we have, as I have already explained, increased pressure and diminished pressure, a series of marks of an oblong form are made in the bottom of the groove, each little mark corresponding to a vibration. The number of such marks, therefore, in a given distance—which, when the velocity of the movement is taken into account, represents a certain interval of time, say the one-fiftieth of a second—corresponds to the pitch of the note; the depth of the marks corresponds to the intensity of the vibration; and the form of the marks to the form of the vibration. Again, suppose a note is sung *diminuendo* to *crescendo*, and again to *diminuendo*, the depth of the groove will vary according to the intensity, at first shallow, gradually becoming deeper till the maximum depth has been reached, and again becoming more and more shallow. These marks, therefore, on the wax cylinder are the representations of the mechanical effects of the vibrations in all respects—number (pitch), depth (intensity or loudness), form (quality). It will be evident, therefore, that if we run over these marks again with the reproducing point, the glass disc will again vibrate to the impulses received by the ups and downs on the cylinder as to reproduce faithfully, but with diminished intensity, the original sound. It is, therefore, an investigation of great interest to study these marks, to reproduce them on such a scale as to enable us to study their form, and to let us see the ups and downs as we would do, suppose we could make a longitudinal section along the bottom of the groove, and looked at the marks sideways.

Before we set ourselves to the study of these marks, let me bring under your notice certain other branches of the investigation. In the first place, we may, to a wonderful extent, increase the volume of tone or loudness of the phonograph by the use of

[1] Abstract of the Science Lecture for 1896, delivered to the Philosophical Society of Glasgow on December 16, 1896, by John G. McKendrick, M.D., F.R.S., Professor of Physiology, University of Glasgow.

resonators. No doubt the *quality* of the tones is best appreciated by carrying the vibrations directly to the vicinity of the drum-head of the ear, as is usually done, by fine tubes; but this method is not always agreeable, and the pleasurable effect is sadly marred by the friction noises. Still the fact that tones are heard best in this way, *as regards their quality*, proves to my mind that the marks on the wax cylinder are accurate representations of the varying intensities of the pressures caused by the sound waves. Resonators, such as the large one you now see, increase the volume of tone, and you will notice how accurately the tones are reproduced.

Now, let us see what we can make of the marks. I have endeavoured to study the marks on the wax cylinder in three different ways—by casts, by photographs, and by mechanical devices.

As regards the first method—taking casts, which was also attempted by Hermann and Boeke—the results were not satisfactory. The most efficient method followed by me was to paint in the cylinder, with a camel-hair brush, a layer of celloidin dissolved in ether. This soon hardened, and the film could then be peeled off. The thin film thus obtained was then inverted on the stage of a microscope, and the marks were seen in relief. A photograph of the marks thus obtained is now on the screen (Fig. 1).

The depressions are well seen, and their differences as regards length are obvious. The method has the disadvantage of flattening out the marks.

I took numerous photographs, with the aid of the microscope and camera, of portions of the surface of the cylinder on which were records of many instruments and of the voice. I now show you on the screen examples of such records (Fig. 2).

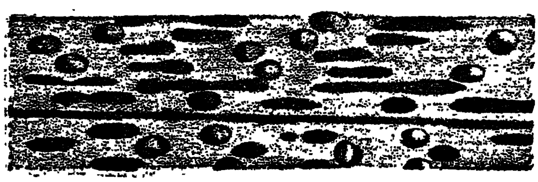

Fig. 1.—Celloidin cast (magnified) of marks on wax cylinder. Portion of record of a military band.

Each figure, from above downwards, represents the $\frac{1}{5}$th of an inch on the surface of the wax magnified fourteen diameters. The grooves seen in each figure are, on the wax cylinder, $\frac{1}{200}$th inch apart, and the length of the groove, from above downwards, represents in time the $\frac{1}{64}$th second—that is to say, when each tracing was recorded, the sapphire point of the recorder travelled over the distance represented in magnified proportions in the $\frac{1}{64}$th part of a second. By counting the number of indentations or marks, which in a photograph have a curious appearance of being in relief, one can at once determine approximately the pitch of the tone, the vibrations of which make the impression. The tones highest in pitch were obtained from the piccolo and the xylophone. Here the pitch was about 1920 vibrations per second. In Fig. *A* we have a picture of the vibrations produced by the tones of the violin, and it will be seen that they vary in character. Sometimes the marks are a little apart, and at other times they blend into each other, the mark widening out as the receding point cut into the wax and then contracting as it receded. It is to be borne in mind that even when the glass disc is not vibrating, the recorder ploughs a groove on the cylinder, and when the glass disc vibrates each vibration cuts deeper into the groove. The figure of the vibration of the tones of a flute (*B*) shows moniliform markings, indicating that the disc may not, in some instances, return to its position of rest for a short time. Sometimes the intensity of the tone is so great as to cause, after each deeply ploughed groove (as will be seen in the figure of the vibrations of the tones of an organ, *D*), a rebound lifting the recorder up to the surface of the cylinder, or even off the surface altogether. This is the explanation of the smooth spaces between the ends of the individual marks.

To obtain a mechanical representation of the curves is a very difficult matter. The difficulties were so far overcome by the device of Jenkin and Ewing with the tinfoil phonograph. The method followed by these observers, which was entirely mechanical, was to cause the disc of the phonograph to record its movements on a drum moved at the same rate as that of the cylinder. As I have already mentioned, Hermann photographed the oscillations of a beam of light reflected from a small mirror connected with the disc of the phonograph, the whole apparatus moving slowly. My method consists in the adaptation of a light lever to the phonograph itself, and so arranged that it (the point of the marker) would travel over all the ups and downs of the phonographic curve on the wax cylinder at an extremely slow rate. The obvious objection to any method of directly recording the ups and downs of the lever is that the inertia of the lever might cause extraneous vibrations, while, at the same time, the smaller marks on the wax cylinder might be missed. These objections, however, were removed by reducing the friction to minimum, and by moving the phonograph cylinder so slowly as to make the movement almost invisible to the naked eye. In this way inertia ceases to give trouble. The first arrangement gave curves of very small amplitude, a specimen of which I now show you.

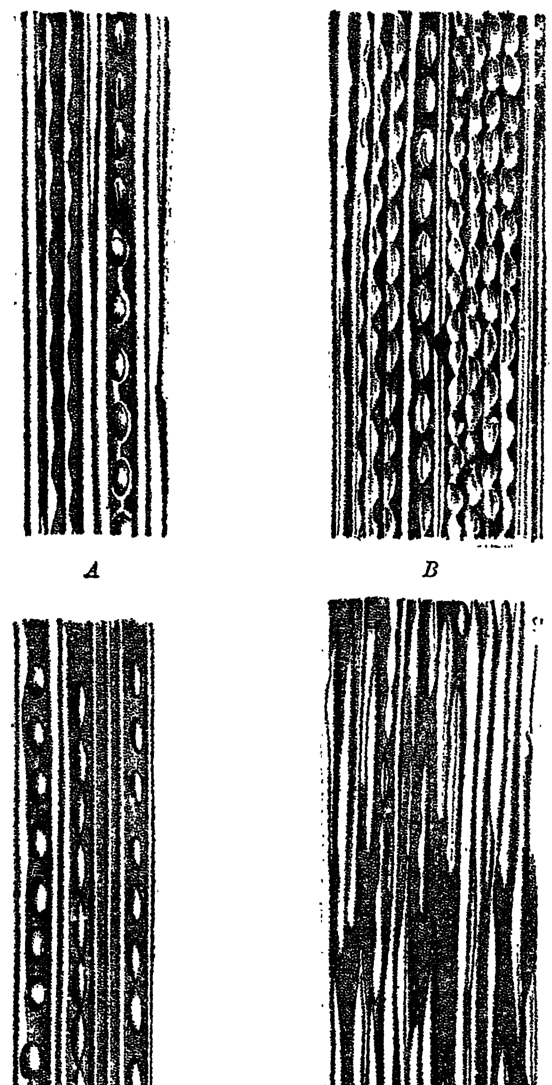

Fig. 2.—From photographs of portions of the surface of the wax cylinder. *A*, violin. *B*, flute. *C*, vowel *o*. *D*, full organ.

Various mechanical arrangements were employed, some of which I described to the Royal Society of Edinburgh in February last.

My attention has since been directed to perfecting a mechanism for obtaining a record of the vibrations.

The instrument now before you, which I shall call a *phonograph-recorder*, traces out, on a large scale, the curves of the indentations on the wax cylinder corresponding to each vibration of sound, and it does so in a way that seems to be highly satisfactory.[1]

Since the apparatus was brought to its present condition, I have been able to record the vibrations of the tones of several instruments, and also the tones of the human voice, both in singing and in speech. Illustrations of these I now show you (Fig. 3).

First, with reference to speech, I wish to point out that when the record of a *word* is examined it is found to consist of a long series of waves, the number of which depends (1) on the pitch of the vowel constituents in the word, and (2) on the duration of the whole word or of its syllables individually. There is not for each word a definite wave form, but a vast series of waves, and, even although the greatest care be taken, it is impossible to obtain two records for the same word precisely the same in character. A word is built up of a succession of sounds, all usually of a musical character. Each of these sounds, if taken individually, is represented on the phonograph-record by a greater or less number of waves or vibrations, according to the pitch of the sound and its duration. The pitch, of course, will depend on the number of vibrations per second, or per hundredth of a second, according to the standard we take, but the number of the waves counted depends on the duration of the sound. As it is almost impossible to utter the same sound twice over in exactly the same fraction of a second, or in the same interval of time, the number of waves counted varies much in different records. The rate per unit of time determines the pitch, the number the duration of the sound. In a *word*, these successive sounds blend into each other, and, in many records, the passage from one pitch to another can be distinctly seen. The speech sounds of a man vary in pitch from 100 to 150 vibrations per second, and the song sounds of a man from 80 to 400 vibrations per second. The sounds that build up a word are chiefly those of the vowels. These give a series of waves representing a variation in pitch according to the character of the vowel sound. In the record of a spoken word the pitch is constantly moving up and down, so the waves are seen in the record to change in length. It is also very difficult to notice where one series of waves ends and where another begins. For example, in the word *Con-stan-ti-nople*, the predominant sounds are those of *o-a-i-o-ill*, and the variation in pitch is observable to the ear if, in *speaking* the word, we allow the sound of the syllables to be prolonged. If we look at the record of the word, we find these variations in pitch indicated by the rate of the waves, or, as the eye may catch this more easily, by the greater or less length of wave, according to the pitch of the sound. The consonantal sounds of the word are breaks, as it were, in the stream of air issuing from the oral cavity, and these breaks (I am not discussing the mechanism at present) produce sounds that have also often the character of vowel sounds. Thus, at the beginning of "Constantinople," we have, as will be observed on pronouncing the syllables very slowly, the sound *ŭkkō*. This sound is represented in the record by a series of waves. Then follow the waves of the vowel *o*. Next we have the sound *nn* (sound through the nose), also represented by a series of waves. Next the hissing sound *ss*, which has first something in it of the vowel *e* or *i*, and then the *iss-s*. This sound also is shown by a series of waves. Then there is *ta*, which has a double series of waves—(1) those for *it* or *t*, and the next for *a*. This passes into the prolonged vowel *a*, this into *in*, this followed by *ti* passing into the vowel *i*, then another *in*, then a long *o*, then a sound like *op*, and, lastly, the sound *ill*, a sort of double-vowel sound. As so many of these sounds have the character of vowels, it is impossible, by an inspection of the record, to say where one set of waves begins and another ends. There are no such breaks corresponding to the consonants; the vibrations of the consonants glide on as smoothly as those of the vowels. The *number* of waves producing a word is sometimes enormous. In "Constantinople" there may be 500, or 600, or 800 vibrations. A record of the words "Royal Society of Edinburgh," spoken with the slowness of ordinary speech, showed over 3000 vibrations, and I am not sure if they were all counted. This brief illustration gives one an insight into nature's method of producing speech sounds, and it shows clearly that we can never hope to reach such records in the sense of identifying the curve by an inspection of the vibrations. The details are too minute to be of service to us, and we must again fall back on the power the ear possesses of identifying the sounds, and on the use of conventional signs or symbols, such as letters of the alphabet, vowel symbols, consonant symbols, or the symbols of Chinese, which are monosyllabic roots often meaning very different things, according to the inflection of tone, the variations in pitch being used in that language to convey shades of meaning.

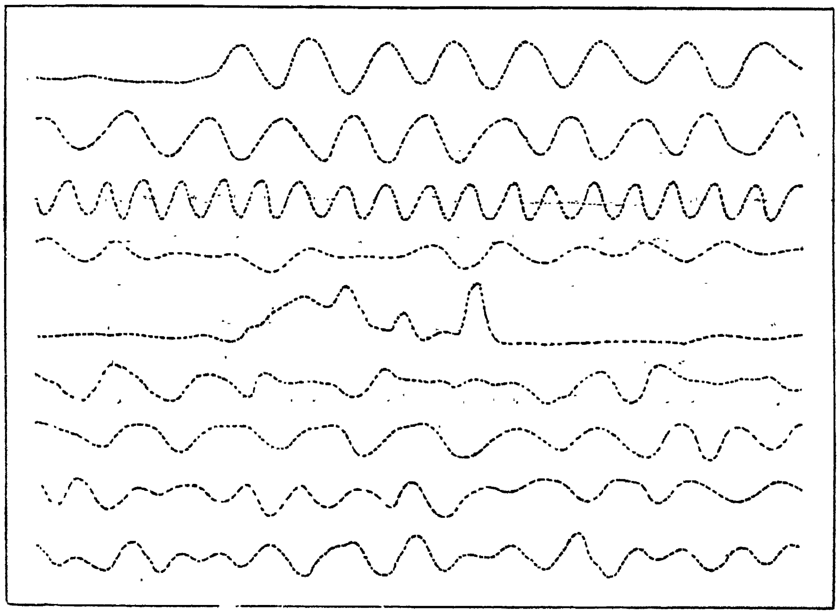

FIG. 3.—Specimens of curves obtained by phonograph recorder. Four inches = 1/120th sec. The curves read from left to right. The lower curve of the flute is continuous with the upper one, to show change of pitch. These curves are given to show the great variety of wave form. They are not sufficiently accurate for analysis. To obtain curves suitable for analysis, the greatest care must be taken.

[1] For a diagram of the apparatus, see *Proc. Roy. Soc. Ed.*, December 7, 1896.

When human voice sounds are produced in singing, especially when an open vowel sound is sung on a note of definite pitch, the record is much more easily understood. Then we have the waves following each other with great regularity, and the pitch can easily be made out. Still, as has been well pointed out by Dr. R. J. Lloyd, of Liverpool, a gentleman who has devoted much time and learning to this subject, it is impossible by a visual inspection of the vowel curve to recognise its elements. Thus two curves, very similar, possibly identical to the eye, may give different sounds to the ear—that is to say, the ear, or ear and brain together, have analytical powers of the finest delicacy. No doubt, by the application of the Fourierian analysis, we may split up the periodic wave into a fundamental of the same period, and a series of waves of varying strength vibrating 2, 3, 4, 5, &c., times faster than the fundamental, and the relative amplitude of each of these may be determined. If all these waves of given amplitude and given phase acted simultaneously on a given particle, the particle would describe the vibration as seen in the original curve. Dr. Lloyd, however, is of opinion that even a Fourierian analysis may not exhaust the contents of a vowel, as it does not take account of inharmonic constituents which may possibly exist. Hermann and Pipping have also been investigating the analysis of vowel tones, and their investigations have revealed many difficulties. Hermann experimented with the ordinary phonograph, and obtained photographs of the movements of the vibrating glass plate. Pipping's curves were not obtained from the phonograph, but from the vibrations of a minute membrane made to represent the drum-head of the ear. His curves show large periodic waves with minute waves on their summits, and they suggest that the large waves may be vibrations due to the membrane itself. I therefore think that argument as to the character of vowels should be based only on records obtained from the phonograph itself, which is furnished with a vibrator that will not record its own periodic vibrations unless the sound be remarkably intense. In ordinary voice production and in ordinary singing, the vibrator of the phonograph faithfully records only the pressures falling upon it—no more and no less.

I shall now show you another method of recording, not the individual vibrations of the phonograph, but the variations in intensity of the sounds of the phonograph—the intensities of individual notes and chords. I was led to use this method by becoming acquainted with an instrument devised by Prof. Heurthle, of Breslau. He has succeeded in recording the vibrations of the sounds of the heart. I saw that his instrument was very useful, and I adapted it to the particular purpose in hand. Heurthle's instrument is an electro-magnet acting on a metal plate connected with the elastic membrane of a tambour. Another drum is connected with the first by an india-rubber tube. The metal plate of the first tambour is pulled down by the electro-magnet; thus the air is rarefied in the tube and in both tambours, and the lever of the second tambour moves. The next instant the lever flies back. We shall now connect Graham's variable resistance apparatus with the phonograph. As sound waves fall on it, a change is produced in the current passing through the electro-magnet; the latter acts on its tambour; a variable pressure is communicated to the other tambour; and if the lever of the latter is brought against a revolving drum, a tracing is obtained. I show you a little bit of such a tracing (Fig. 4).

Each note and each chord is recorded, so that you get a mechanical tracing of the variations of intensity. Now this experiment suggested another of a different kind. Suppose I send the current not only through the variable resistance apparatus above the disc of the phonograph, but also through the primary coil of an induction machine. The wires from the secondary coil pass to two platinum plates dipped in weak salt solution. I now set the phonograph going; and when I put my fingers into the beakers containing salt solution, I *feel* the intensity of every note. The variation of intensity, the time, the rhythm, and even the expression of music, are all felt. I shall now place on the mandril of the phonograph a cylinder on which has been recorded another piece of music, with a faster *tempo*. I now feel a series of electrical thrills corresponding to every variation of intensity of sound coming from the phonograph. That method shows that the nerves of the skin can be stimulated by irritations coming to it at the rate of the notes and chords of rapid music. Some of the notes produced by the phonograph do not last longer than the five-hundredth or six-hundredth part of a second, but they are quite sufficient to stimulate the nerves of the skin, and, as I have pointed out, you can appreciate the variations of intensity. You can *feel* the long drawn-out notes from the saxhorn or trombone. You feel the *crescendo* and *diminuendo* of rhythmic movement, and you can estimate the duration of the note and chord. You feel even something of the expression of the music. It is rather a pity to say than even expression is mechanical. It is undoubtedly mechanical when you deal with the records of the phonograph. A number of interesting questions of a physiological nature are suggested by this experiment. The skin is not a structure that can analyse tone or distinguish pitch; it cannot tell you the number of vibrations, although there is a curious approach to it. While it is not by any means accurate, you can distinguish tones of low pitch—very low tones—by a feeling of "intermission." Experimenting in this way, you may stimulate by interrupting this circuit at the rate of 30 or 40 or 50 breaks per second, and yet the skin will tell you the individual breaks; but when you get above that number you lose the consciousness of the individual breaks, and you have a more or less continuous sensation. The phonograph does not necessarily give you 50 or 60 *stimuli* to produce a sensation of a tone; you do not require that number. I found that 8 or 10 per second may give you the sensation for a tone of any pitch. In the same way you may be able to notice a slight difference up to perhaps 50 or 60, but above that the sensation seems continuous. It is not the number of *stimuli* that determine pitch, but the rate at which the *stimuli* affect the sense organ, whether it be ear or skin. Then the question arises, What is it in the skin that is irritated? It is not the corpuscles. They have to do with pressure. There is no organ for the sense of temperature. You may say that the feeling is muscular. Possibly it may be so; but the effect is most marked when the current is so weak as to make it unlikely that it passes so deep as to reach the muscles.

This experiment suggests the possibility of being able to communicate to those who are stone deaf the feeling, or, at all events, the rhythm of music. It is not music, of course, but, if you like to call it so, it is music *on one plane and without colour*. There is no appreciation of pitch or colour or of quality, and there is no effort at analysis, an effort which, I believe, has a great deal to do with the pleasurable sensation we derive from music. In this experiment you have the rhythm which enters largely into musical feeling. Recently, through the kindness of Dr. J. Kerr Love, I had the opportunity of experimenting with four patients from the Deaf and Dumb Institution, one of whom had her hearing till she was eleven years of

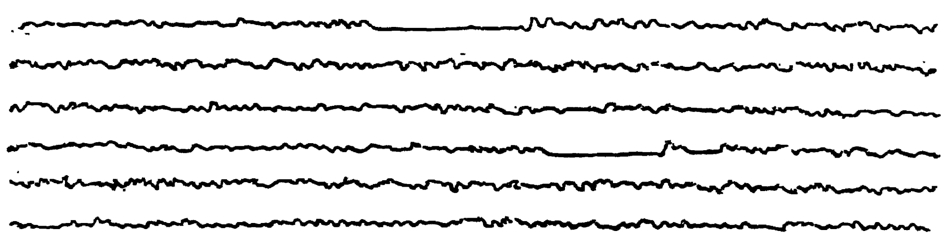

FIG. 4.—Portion of a record of the time and intensity of music played by a military band. Each curve represents a note or chord. The curves are read from right to left. The cylinder in which the record was taken was moving slowly, about 1 inch per second.

age, and then she became stone deaf. This girl had undoubtedly a recollection of music, although she does not now hear any sound. She wrote me a little letter, in which she declared that *what she felt was music*, and that it awakened in her mind a conscious something that recalled what music was. The others had no conception of music, but they were able to appreciate the rhythm, and it was interesting to notice how they all, without exception, caught up the rhythm, and bobbed their heads up and down, keeping time with the electrical thrills in their finger-tips.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The establishment of a University Lectureship in Experimental Psychology was opposed in the Senate, but it has now been carried by a very large majority.

Thirty-three men and three women have obtained a first-class in the Natural Sciences Tripos, Part I. In Part II. the first-class includes eleven names.

Prof. Allbutt, F.R.S., has been appointed to represent the University at the International Medical Congress to be held at Moscow in August.

The Harkness Scholarship in Geology and Palæontology has been awarded to Mr. R. H. Kitson, of Trinity College.

The Observatory Syndicate report that, Mr. Newall's term of office as Observer having expired, he has generously undertaken to continue to give his services without stipend for another term of five years. They think, however, that the provision of a stipend for the Newall Observer is an urgent claim on the funds of the University. In its present impoverished state the University is much indebted to Mr. Newall for his devoted and efficient aid in the department of physical astronomy. The portion of the catalogue of the *Astronomische Gesellschaft* allotted to Cambridge has now been published, after twenty-five years' work carried out for the most part by Mr. A. Graham. It refers to the zone 25° to 30°, and contains the places of 14,464 stars, obtained from about 47,570 observations. A new photographic telescope is being made for the observatory by Sir Howard Grubb, and the building for its accommodation will be taken in hand this summer.

The Special Board for Physics and Chemistry have, as was anticipated, withdrawn their proposals that the laboratory note-books of candidates for the first part of the National Sciences Tripos should be submitted to the examiners. They adhere to the proposal, in a modified form, as regards the second part of the examination. It is, however, provided that no marks shall be assigned for the note-books, the inspection of which is intended simply to give some guidance to the examiners in estimating the value of the practical part of the examination.

The first dissertations offered by advanced (post-graduate) students as candidates for the B.A. degree have been submitted and approved. Mr. J. S. E. Townsend and Mr. E. Rutherford have each offered memoirs on electrical subjects which have been honoured by publication in the *Phil. Trans.* of the Royal Society, and the Degree Committee record their opinion that the work submitted "is of distinction as a record of original research." These gentlemen have accordingly received the University Certificate of Research, and the degree of Bachelor of Arts, under the new regulations for graduates of other Universities.

The Hutchinson Studentship has been awarded to Mr. V. H. Blackman, of St. John's College, for botanical researches on Algæ. The Hockin Prize for Electricity has been awarded to Mr. W. A. D. Rudge, of the same college, a student in his first year.

THE University of Dublin has conferred the honorary degree of Doctor of Science upon Dr. Wilhelm His, Professor of Anatomy in Leipzig University, and Prof. Ramsay.

THE will of the late Mr. J. H. R. Molson has been admitted to probate at Montreal. It assigns 100,000 dollars to McGill University, 30,000 dollars to the Frazer Institute, and 10,000 dollars to Bishop's College School at Lennoxville.

ON Thursday last a farewell address was presented to Prof. Sollas, F.R.S., by past and present students of geology in Trinity College, Dublin. Prof. Sollas is leaving Dublin for Oxford, where he succeeds the late Prof. Green as professor of geology.

ENDOWMENTS recently received by Rutgers College increase the fund nearly 50,000 dollars, and include 5000 dollars from the Vice-President of the United States; 10,000 from Mrs. Winants, of Brooklyn; 5000 each from Mr. Frederick Frelinghuysen, of Newark, and Mr. Samuel Sloan and Mr. Richard Schlett, of New York, with the promise of 10,000 more from the latter; and 3234 from the Alumni Association.

IN order to obtain an accurate conception of the growth of Harvard University, Prof. C. S. Minot has compiled a table showing the gifts of money to Harvard College from 1868 to 1896, and he makes it the subject of a contribution to the Harvard *Graduate's Magazine* for June. It appears from this article that Harvard University has received annually during the past twenty-eight years in round numbers 330,000 dollars. The educational efficiency of the University has increased even faster than its endowment. It is held that seven scientific departments, in which the Medical, Dental, and Veterinary Schools have a common interest, need immediate endowment. The departments are: (1) anatomy (human and comparative); (2) physiology; (3) histology and embryology; (4) pathology; (5) bacteriology; (6) pharmacology; (7) hygiene. Each of the seven departments needs to be organised on the minimum basis of 300,000 dollars, making in all an endowment of 2,100,000 dollars. If the gifts continue as heretofore, six years would suffice to furnish the required amount. It is suggested that the development of the seven departments mentioned would be facilitated by the consolidation of the Medical, Dental, and Veterinary Schools under a single Faculty.

THE following are among recent appointments:—Mr. J. R. Campbell, of the Glasgow Technical College, to be lecturer in agriculture at the Harris Institute, Preston; Prof. W. T. Engelmann, of Utrecht, to succeed the late Prof. Du Bois Reymond in the chair of physiology in the University of Berlin; Dr. W. B. Pillsbury to be instructor in psychology in the University of Michigan; Dr. C. E. Seashore to be assistant in psychology in the University of Iowa; Mr. S. I. Franz to be assistant in psychology in Columbia University; Prof. William S. Franklin to be professor of physics and electrical engineering at Lehigh University; Dr. John Marshall to be professor of chemistry in the medical department of the University of Pennsylvania; Miss Bertha Stoneman to be professor of botany in the Huguenot College for Women in Cape Colony; Prof. J. L. Prevost to be professor of physiology in the University of Geneva; Dr. P. Francotte to be professor of embryology and Dr. P. Stroobant professor of astronomy in the University of Brussels; Dr. J. J. Zumstein to be professor of anatomy in the University of Marburg; Dr. Fuchs, privat-docent in palæontology and director of the geological section of the Natural History Museum at Munich, to be assistant professor; Dr. H. Baum, prosector and privat-docent in osteology at the Dresden Technical High School, to be professor; Dr. W. Ule, privat-docent in geography at Halle, to be professor; Dr. J. J. Ptaschicky to be professor of geometry at St. Petersburg; Dr. A. O. Kihlman to be assistant professor of botany at Helsingfors; Dr. Heim to be assistant professor of hygiene at Erlangen; Dr. Alex. Bittner to be chief geologist of the K. K. geologischen Reichsanstalt at Vienna; also, at the same institution, G. Geyer to be geologist, G. v. Bukowski and August Rosiwal to be adjunkten, and Dr. J. Dreger, F. Eichleiter, Dr. F. v. Kerner, and Dr. J. J. Jahn to be assistants.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, June 25.—Mr. Shelford Bidwell, President, in the chair.—A paper by Mr. Sutherland, on a new theory of the earth's magnetism, was taken as read.—Dr. Kuenen described some experiments on critical phenomena, made in continuation of a research on the condensation and critical phenomena of mixtures of ethane and nitrous oxide, the results of which were published last year. The author now investigates mixtures of ethane and acetylene, and mixtures of ethane and carbonic acid, and finds for them similar properties to those of the mixtures of ethane and nitrous oxide. The first part of the paper refers to the preparation of ethane, and the effect of impurities on its vapour-pressure, and critical constants.

Ethane from ethyl iodide is not very pure, it has generally several per cent. of an admixture of a substance of higher critical temperature and higher density than ethane; this substance is probably butane. Ethane from sodic acetate, by electrolysis, is nearly pure; the method of preparation is described by the author. The pressure and corresponding volumes during condensation are given for this substance at various temperatures. In the former paper, above referred to, instances are mentioned of mixtures having critical temperatures *below* those of the component substances. The only instance of critical temperatures *above* those of the components, seem to be those relating to mixtures of carbonic acid and acetylene. According to an experiment of Dewar's, however, a mixture of $\frac{1}{2}CO_2$ and $\frac{1}{2}C_2H_2$ has a critical temperature of 41° C., those for carbonic acid and acetylene being 31° and 37° respectively. The present investigation contradicts this result. Dewar may not have taken sufficient precaution in avoiding errors of retardation. Mixtures of carbonic acid and acetylene have critical temperatures between those of the component pure gases. The diagram connecting temperature and volume shows that the plait-point curve is a line with small curvature; the border-curve is relatively narrow. An instance of a critical temperature above those of the components, for this mixture, has not yet been proved. Theory indicates that this phenomenon probably occurs for mixtures having a minimum vapour-pressure at low temperature. Critical temperatures below those of components, seem to occur for mixtures having a maximum vapour-pressure; as for nitrous oxide and ethane. The law connecting the two phenomena is deduced from van der Waal's theory. As a further application of this theory, it is shown that in consequence of certain coincidences between the real border-curve and the hypothethical border-curve, the critical point of the maximum mixture may be determined in exactly the same way as for a single substance. A remark is added with regard to the condensation of such substances as exhibit changes of molecular systems. If an association takes place of molecules to more complicated systems, van der Waal's formula does not apply. Dr. S. P. Thompson asked whether diagrams characteristic of cyanogen had been obtained. Its remarkable polymerism suggested an interesting case for critical phenomena. Dr. Kuenen thought such a substance might be worth investigation.—A paper by Dr. Barton, on the attenuation of electric waves in wires, was taken as read.—Mr. G. F. C. Searle read a paper on the steady motion of an electrified ellipsoid. The first part of the investigation is printed in the *Phil. Trans. Roy. Soc.*; it contains the principles required in the solution of problems with respect to moving electrical charges. The second part, now presented to the Physical Society, deals with the motion of a charged ellipsoid; the treatment is entirely mathematical. When any system of electric charges moves with uniform velocity through the æther, the electro-magnetic field, referred to axes moving forward with the charges, can be completely defined by means of a quantity of which the electric force and the magnetic force are simple functions. Another vector concerned in the problem is the mechanical force experienced by a unit charge moving with the rest of the system. A distribution of electricity on the surface of a charged body such as to give zero distribution at all points inside the surface is an equilibrium distribution. Since the mechanical force vanishes inside the surface, it is shown that on the outside of the surface the mechanical force is perpendicular to the surface, and the above-mentioned function is constant over the surface, and the distribution on an ellipsoid is the same for motion as for rest. When a charged sphere is at rest it produces the same effect as a point-charge at its centre. If the sphere is in motion it produces the same effect as a uniformly-charged line whose length bears to the diameter of the sphere the same ratio as the velocity of the sphere bears to the velocity of light. When the sphere moves with the velocity of light, the line becomes the diameter of the sphere; the same is true for an ellipsoid. At the velocity of light, the charge on any surface is in equilibrium, whatever the distribution. The force between two charges moving with the speed of light, is zero. The lines of electric force for a charged sphere in motion are not radial; they form a series of hyperbolas. The author proceeds to calculate the total energy possessed by an ellipsoid when in motion along its axis of figure. Expressions are given (1) for the energy of a Heaviside ellipsoid; (2) for a sphere; and (3) for a very slender ellipsoid. In all cases the energy becomes infinite when the charges move at the velocity of light. It would seem impossible to make a charged body move at a greater speed than that of light. Prof. Perry said the paper would help to solve many problems connected with the effect of the rotation of the earth upon electrical surface charges. An expression might be found for the mechanical and magnetic forces due to the motion of a charge at any point of the earth's surface. At the equator a point moves at different velocity at midday to its midnight velocity; it may now be possible to determine the magnetic and mechanical effects due to electrical charges at equatorial points. Mr. Blakesley asked whether, in calculating the mutual action of two charged particles, proceeding at the velocity of light, it was assumed that the lines of motion were parallel. Mr. Searle said he had always considered parallel lines of motion; he could not say whether the force would be zero in any other case. The results arrived at in the paper could be applied to problems connected with distributions of terrestrial charges.—The President proposed votes of thanks to the authors; the meeting then adjourned until November.

Chemical Society, June 3.—Prof. Dewar, President, in the chair.—The following papers were read:—On the thermal phenomena attending the change of rotatory power of freshly-prepared solutions of certain carbohydrates; with some remarks on the cause of multirotation, by H. T. Brown and S. Pickering. Freshly prepared solutions of dextrose, lævulose, and milk-sugar contain the sugar as an unstable α-modification, which gradually changes into a stable β-modification; this change is made apparent by a change of specific rotation, and, as the authors show, is accompanied by evolution of heat, the quantity of which has been measured.—On the thermo-chemistry of carbohydrate-hydrolysis: (1) The hydrolysis of starch by vegetable and animal diastase; (2) the hydrolysis of cane-sugar by invertase, by H. T. Brown and S. Pickering. The authors have determined by direct measurement the heat evolved in the hydrolysis of starch by malt-diastase, pancreatic-diastase, Taka-diastase and saliva, and in the hydrolysis of cane-sugar by invertase.—Optical inversion of camphor, by F. S. Kipping and W. J. Pope. It is shown that during the sulphonation of *d*-camphor, part of it is converted into *l*-camphor.—Derivatives of camphoric acid. Part ii. Optically-inactive derivatives, by F. S. Kipping and W. J. Pope.—Racemism and pseudoracemism, by F. S. Kipping and W. J. Pope. The authors show that a number of apparently racemic compounds really consist of intercalations of crystals of the two enantiomorphously related components; the term pseudoracemic is applied to such substances of which several are described in detail.—Note on some new gold salts of the Solanaceous alkaloids, by H. A. D. Jowett. Hyoscine hydrobromide combines with auric chloride and bromide, giving salts of the composition X, HBr, $AuCl_3$ and X, HBr, $AuBr_3$.—Production of camphenol from camphor, by J. E. Marsh and J. A. Gardner. Camphenol, an isomeride of camphor, is obtained by the action of strong sulphuric acid on chlorocamphene, camphene dichloride, and turpentine dihydrochloride.—Preliminary note on the oxidation of fenchene, by J. A. Gardner and G. B. Cockburn. Cis-camphopyric acid is produced on oxidising fenchene with dilute nitric acid.—Apiin and apigenin, by A. G. Perkin. The author produces experimental evidence which renders it probable that apigenin is a hydroxy-derivative of chrysin, the colouring matter of poplar buds.—Rhamnazin, by A. G. Perkin and H. W. Martin.—Experimental verification of van 't Hoff's constant in very dilute solution, by M. Wildermann.—The isomeric dibromoethylenes, by T. Gray. The author has been unsuccessful in his attempts to prepare a stereo-isomeride of ordinary symmetrical dibromoethylene; he considers the latter to be the trans-compound.

Entomological Society, June 2.—Mr. R. Trimen, F.R.S., President, in the chair.—The President referred to the great loss which the Society had sustained by the death of Dr. Fritz Müller, one of its Honorary Fellows, and to his distinguished services in the cause of entomological science, and especially in forwarding the theory of the origin of species.—Dr. Chapman exhibited the larva of *Eriocephala allionella*.—Mr. Jacoby exhibited a fine example of the large Hepialid, *Leto venus*, from Plettenberg Bay, South Africa. The President said that the insect afforded an interesting case of localised distribution, being confined to an area of about fifty by fourteen miles, whereas the larva fed in the wood of *Virgilia capensis*, a common and widely-distributed leguminous tree. The insect was very conspicuous, and could not have been overlooked in other localities.—Mr. Burr showed a pair of gynandromorphous earwigs, *Chelisoches*

morio, Fabr., from Java, with ordinary males and females for comparison. In both specimens the right branch of the forceps was of the male, and the left branch of the female form.—The Hon. Walter Rothschild exhibited a series of specimens of *Eudæmonia brachyura*, Drury, and *E. argiphontes*, Kirby, to show the differences between these two West African Saturniid moths. The distinctness of the latter species had been doubted, as until recently it was only known by the unique examples in the Dublin Museum, and the three published figures of these were materially different from each other. A comparison of the series exhibited showed the two species to be abundantly distinct.—Mr. Kirkaldy exhibited fifty specimens of *Notonecta glauca*, Linn., to show the extreme range in size and colour of this widely-distributed species.—The discussion on mimicry and homœochromatism in butterflies was then resumed by Dr. Dixey, who replied to the comments of Prof. Poulton and Mr. Blandford on his paper. He did not regard the phenomenon of reciprocal convergence as necessarily a demonstrable feature in Müllerian mimicry; it was merely potential. With respect to mimetic Pierinæ, he did not consider that they were invariably protected, but that, in certain cases, they were shown to be so by the indications of convergence exhibited by the models. Mr. Elwes thought, from his personal experience as a collector, that there was too much assumption about both the Batesian and Müllerian theories. In many supposed cases he doubted whether the so-called models were protected by taste or smell. He had previously referred to the extraordinary superficial resemblance between two Pieridæ found in the high Andes of Bolivia, and two others found at similar elevations in Ladak, and was inclined to think that similar conditions of environment produced similar effects. Mr. J. J. Walker, Sir George Hampson, and Colonel Yerbury gave evidence, from personal experience in the Tropics, as to the extreme rarity of butterfly-destruction by birds. The President admitted its rarity in Africa, but stated that he had seen birds, especially the Drongo shrike, chasing butterflies. Mr. Blandford called attention to a recent paper by M. Piepers, who, as the result of twenty-eight years' observation in the Malay region, had seen four instances only of butterflies, two of which belonged to the "protected" genus *Euplœa*, being attacked by birds, and had been driven to the conclusion that the phenomena of mimicry had nothing to do with natural selection.—Papers were communicated by the Rev. F. D. Morice, on new or little-known Sphegidæ from Egypt, and by Prof. J. R. Grote, on changes in the structure of the wing of butterflies.

Geological Society, June 9.—Dr. Henry Hicks, F.R.S., President, in the chair.—The Cretaceous strata of County Antrim, by Dr. W. Fraser Hume. The paper, which dealt with the Irish Cretaceous strata, was divided into four parts, viz.: I. A detailed account of the principal subdivisions, their local distribution, and characteristic fossils. The area occupied by these rocks is separated into five divisions, each marked by special lithological and palæontological features. The main lithological features are displayed in sections between Lisburn and Belfast; they are (1) glauconitic sands (a blue-green rock rich in glauconite); (2) glauconitic marls; (3) yellow sandstones (a light calcareous sandstone); (4) chloritic sands and sandstones of the *Exogyra columba*-zone (yellow-green sands and sandstones); and (5) white limestone. II. Chemical and micromineralogical examination of the lithological types. The glauconitic sands are characterised by the abundance of glauconite (23 per cent. $CaCO_3$), showing evidence of having been formed in the interior of foraminiferal shells; the glauconitic marls by an abundance of spheres and rods of pyrites; the yellow sandstones by a series of heavy minerals, notably rutile, zircon, tourmaline, kyanite, and perfectly-formed crystals of garnet; the *Inoceramus*-zone contains delicate glauconitic mesh-works of hexactinellid sponges and silicified portions of *Inoceramus* and brachiopoda, besides an abundant series of heavy minerals: in the chloritic chalk above the glauconitic sponge-casts become very abundant, associated with delicate casts of foraminifera; the white limestone itself has scarcely any residue. The analyses show that the percentage of carbonate of lime increases steadily from base to summit, the glauconitic marls alone being an exception. III. This section dealt with the stratigraphical conclusions. IV. General questions.—An account of the Portraine inlier, by C. I. Gardiner and S. H. Reynolds.—Some igneous rocks in North Pembrokeshire, by J. Parkinson.

Zoological Society, June 15.—Dr. St. George Mivart, F.R.S., Vice-President, in the chair.—Dr. Arthur Keith exhibited a series of lantern-slides showing the arrangement of the hair and some other points of interest in the Orang-Outang (*Simia satyrus*) that had lately died in the Society's Gardens.—Mr. Oldfield Thomas read an account of the mammals obtained by Mr. John Whitehead during the last three years in the Philippine Islands. During this expedition the peculiar mammal-fauna of the mountains of northern Luzon had been discovered, and Mr. Thomas had already described no less than five new genera and eight new species belonging to it. The paper read contained a detailed account of the whole of Mr. Whitehead's collection.—A communication was read from Prof. T. W. Bridge, on the presence of ribs in *Polyodon* (*Spatularia*) *folium*.—Mr. R. I. Pocock read a paper on the spiders of the suborder *Mygalomorphæ* from the Ethiopian region contained in the collection of the British Museum. Many new genera and species were described, the most interesting being the new genus *Cyclotrematus*, containing two new species collected in Mashonaland by Mr. J. ffolliott Darling, *Stasniopus oculatus*, sp. nov., from Bloemfontein, and *Moggridgea whytei*, sp. nov., obtained by Mr. A. Whyte on the Nyika Plateau. The discovery of new stridulating organs, consisting of modified setæ, lying between the mandible and the maxilla in *Harpactina*, was also alluded to.—A communication was read from Miss Emily M. Sharpe on the butterflies collected in the neigbourhood of Suakim by Mr. Alfred J. Cholmley. Thirty species were enumerated, and the localities where the specimens were collected and the dates of their capture were recorded.—A communication was read from Mr. Walter E. Collinge, describing two new slugs of the genus *Parmarion* from Borneo, viz. *P. everetti* and *P. intermedium*.—A communication was read from Dr. Alphonse Dubois, containing notes on certain specimens of birds in the Brussels Museum, and describing a supposed new species of woodpecker from Borneo, proposed to be called *Tiga borneonensis*.—A communication from Mr. D. J. Scourfield contained some preliminary notes and a report on the Protozoa, Tardigrada, Acarina, and Entomostraca collected by Dr. J. W. Gregory during his expedition to Spitzbergen in 1896.—A communication from Mr. David Bryce contained a report on the Rotifera collected by Dr. Gregory's expedition in Spitzbergen.—Mr. G. A. Boulenger, F.R.S., gave a list of the reptiles and batrachians collected in Northern Nyasaland by Mr. Alex. Whyte, and presented to the British Museum by Sir Harry Johnston, K.C.B. Thirty-six species of reptiles and fifteen species of batrachians were enumerated, of which the following were described as new:—*Lygosoma johnstoni*, *Glypholycus whytii*, *Anthroleptis whytii* and *Hylambates johnstoni*.—Dr. Fowler communicated a paper on the later development of *Arachnactis albida* (M. Sars) and on *A. boweni*, sp. nov., being the third instalment of the "Contributions to our Knowledge of the Plankton of the Faeroe Channel."

Royal Meteorological Society, June 16.—Mr. E. Mawley, President, in the chair.—A paper, by Mr. R. C. Mossman, on the non-instrumental meteorology of London, 1713–1896, was read by the Secretary. The author has gone through the principal meteorological registers and weather records kept in the metropolis, and in this paper discusses for a period of 167 years the notices of thunderstorms, lightning without thunder, fog, snow, hail and gales. The average number of thunderstorms is 9·7 per annum, the maximum occurring in July, and the minimum in February. The average number of fogs is 24·4, and of "dense" fogs 5·8 per annum. The decadal means show that there has been a steady and uninterrupted increase of fog since 1841. The average number of days with snow is 13·6 per annum. The snowiest winter was that of 1887–8, with forty-three days, while in the winter of 1862–3 there is not a single instance of a snowfall. The mean date of first snowfall is November 9, and of last snowfall March 30. Hail is essentially a spring phenomenon, reaching a maximum in March and April; the minimum is in July and August. The average number of days with hail is 5·9 per annum.—Mr. C. Harding gave an account of the hailstorm which occurred in the south-west of London on April 27. This accompanied a thunderstorm, in which the lightning was very vivid. The hail lasted only about twenty minutes, from 6.30 to 6.50 p.m., and in that short space of time the melted hail and rain amounted to about an inch of water. The districts affected by the hail were Tooting, Balham, Streatham, Tulse Hill, and Brixton. The ground was quite white with the hailstones, which in some places remained unmelted the whole of the next day. Much damage was done to fruit-trees and shrubs.

PARIS.

Academy of Sciences, June 21.—M. A. Chatin in the chair.—On the Abelian functions, by M. H. Poincaré.—Expression of the small transverse components of velocity in the gradually varied outflow of liquids, by M. Boussinesq.—Note on the seventh volume of the "Annales de l'observatoire de Bordeaux," by M. Lœwy.—Examination of some spectra, by M. Lecoq de Boisbaudran. A discussion of some points raised by MM. Eder and Valenta on the spectrum of gold.—Note by M. Pomel accompanying the presentation of his work on the "Mammifères quaternaires fossiles algériens, monographie des Porcins."—M. Hatt was nominated a member in the Section of Geography and Navigation, in the place of the late M. d'Abbadie.—On the universal deluge, by M. F. E. Paumier.—On the movement of the perihelia of Mercury and Mars, and of the node of Venus, by M. Simonin.—On the surfaces which can, in several different movements, develop a family of Lamé, by M. Eugène Cosserat.—Observations by M. Darboux on the preceding communication.—On a class of hyperabelian functions, by M. H. Bourget.—On certain equations analogous to differential equations, by M. C. Bourlet.—Observations on the preceding communication, by M. Appell.—On a class of ds^2 of three variables, by M. Levi-Civita.—Application of photography to the measurement of indices of refraction, by MM. Auguste and Louis Lumière. The plate, the refractive index of which is to be measured, is coated very thinly with the sensitive emulsion. It is then faintly illuminated by rays from a point (a minute hole in a sheet of metal). Under these circumstances a halo is produced, arising from reflexion at the back of the plate, the edges of which are quite sharp, and whose diameter determines the refractive index. To apply this method to the measurement of the refractive index of liquids, the back of the plate is wetted with the liquid, and backed with a piece of black velvet soaked in the same. Data are given for water and glycerine.—On a new self-registering apparatus for submarine cables, by M. Ader. The improvements consist of devices for reducing the inertia of the moving parts. The wire carrying the cable current forms part of a minute dynamometer, placed in a powerful magnetic field formed by a permanent magnet. The oscillations are recorded photographically; a practical trial over the Brest-St. Pierre and Marseilles-Algiers cables showed that the number of signals transmitted per minute was from 1·5 to 2·7 times that of the maximum obtainable by the Kelvin recorder.—On a new electrolytic condenser of large capacity and on an electrolytic current rectifier, by M. Ch. Pollak. By passing firstly an alternating current and then a continuous current between aluminium electrodes in an alkaline solution, the plates become coated with an extremely thin crystalline deposit of oxide, which is practically non-conducting. A condenser is thus obtained in which the oxide film acts as the dielectric, and the extreme thinness of this film is the cause of its very high capacity.—Double and triple lines in spectra produced under the influence of an external magnetic field, by M. Zeeman.—On the sulpho-antimonites of potassium, by M. Pouget.—On the fluidity of fused nickel, by M. Jules Garnier.—Combinations of tellurium iodide and bromide with the corresponding hydracids, by M. R. Metzner.—The electrolytic analysis of brass and bronze, by M. Hollard.—The reaction between formaldehyde and potash, by M. Delépine. A thermo-chemical study.—Destruction of organic matter in toxicological researches, by M. A. Villiers. The use of manganese salts with a mixture of hydrochloric and nitric acids is recommended.—On caffotannic acid, by MM. P. Cazeneuve and Haddon.—Coleopterine, a red pigment in the wing shells of some Coleoptera, by M. A. B. Griffiths.—On the decolorisation of wine; new interpretation based upon the function of iron salts, by M. H. Lagatu.—On the subrenal capsules, the renal organs, and lymphoidal tissue of lophobranchial fishes, by M. E. Huot.—On a new Copepod, by M. Émile Brumpt. The new species is found as a parasite of *Polycirrus aurontiacus* (Grube), and is named *Saccopsis Alleni*.—Action of mineral salts upon the development and structure of some graminæ, by M. Ch. Dassonville. The graminaceæ studied, when they were cultivated in pure water, showed a more feeble development in all the tissues, but a much greater lignification.—On the propagation of *Pseudocommis vitis* (Debray), by M. E. Roze.—On the discovery of new strata containing fossils of mammals in the Island of Corsica, by M. Charles Depéret.—On some localisations of morphine in the organism, by MM. A. Antheaume and A. Mouneyrat.—New experiments on nerve irritation by electric rays, by M. B. Danilewsky.—The diurnal oscillatory movement of the atmosphere, by M. Dechevrens.—On the tornado of June 18, at Asnières, and the storm phenomena observed on the same day, by M. Joseph Jaubert.—On the tornado of June 18, by M. Léon Teisserenc de Bort.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—The Yew Trees of Great Britain and Ireland: Dr. J. Lowe (Macmillan).—Elektrische Ströme: Prof. E. Cohn (Leipzig, Hirzel).—The New Africa: Dr. A. Schulz and A. Hammar (Heinemann).—The Life-Histories of the British Marine Food-Fishes: Prof. McIntosh and A. T. Masterman (C. J. Clay).—Lectures on the Action of Medicines: Dr. T. Lauder Brunton (Macmillan).—Botanische Wanderungen in Brasilien: Dr. W. Detmer (Leipzig, Veit).—Ostwald's Klassiker der Exakten Wissenschaften, Nr. 86, 87 (Leipzig, Engelmann).—Monthly Current Charts of the Atlantic Ocean (London).—Die Mechanik in Ihrer Enwickelung: Dr. E. Mach (Leipzig, Brockhaus).—L'Année Biologique, Première Année 1895 (Paris, Schleicher).—Macmillan's Geography Readers, Book 4 (Macmillan).—Thirty Years of Teaching: Prof. L. C. Miall (Macmillan).

PAMPHLETS.—Die Gesetze der Rotationselemente der Himmelskörper: C. A. Lilje (Stockholm).—The Extinction of War, Poverty and Infectious Diseases (Truelove).—The Science of Speech: A. M. Bell (Washington).

SERIALS.—Engineering Magazine, June (Tucker).—Botanische Jahrbücher, Dreiundzwanzigster Band, 4 Heft (Leipzig, Engelmann).—Journal of the Institution of Electrical Engineers, June (Spon).—Proceedings of the Academy of Natural Sciences of Philadelphia, 1897, Part 1 (Philadelphia).—Sitzungsberichte der K. B. Gesellschaft der Wissenschaften, Math. Naturw. Classe, 1896, i. and ii. (Prag).—Twentieth Annual Report of the Connecticut Agricultural Exploration Station (New Haven).—Archives of Skiagraphy, No. 4 (Rebman).—Good Words, July (Isbister).—Sunday Magazine, July (Isbister).—Longman's Magazine, July (Longmans).—Humanitarian, July (Hutchinson).—Aus dem Archiv der Deutschen Seewarte, xix. Jahrgang, 1896 (Hamburg).—Séances de la Société Française de Physique, 1896, 4e Fasc. (Paris).—Transactions of the Leicester Literary and Philosophical Society, Vol. iv. Part 8 (Leicester).—Manchester Microscopical Society, Transactions and Annual Report, 1896 (Manchester).—Reliquary and Illustrated Archæologist, July (Bemrose).—Contemporary Review, July (Isbister).

BICYCLES AND TRICYCLES.

Bicycles and Tricycles. An Elementary Treatise on their Design and Construction. With Examples and Tables. By Archibald Sharp, B.Sc., Whitworth Scholar, Associate Member of the Institution of Civil Engineers, Mitglied des vereines Deutscher ingenieure, Instructor in Engineering Design at the Central Technical College, South Kensington. With numerous Illustrations. Octavo. Pp. xviii + 536. 565 Figures. Index. (London, New York, and Bombay: Longmans, Green, and Co., 1896.)

IT is difficult to know who to congratulate most, the author of this really valuable work or the public, especially the cycle manufacturing branch of it, for whose edification and improvement it has been written.

The second paragraph of the author's preface so aptly summarises the need for such a book that, in spite of its length, it is worth quoting in full.

"The present type of rear-driving bicycle is the outcome of about ten years' practical experience. The old 'Ordinary,' with the large front driving-wheel, straight fork, and curved backbone, was a model of simplicity of construction, but with the introduction of a smaller driving-wheel, driven by gearing from the pedals, and the consequent greater complexity of the frame, there was more scope for variation of form of the machine. Accordingly, till a few years ago, a great variety of bicycles were on the market, many of them utterly wanting in scientific design. Out of these, the present day rear-driving bicycle, with diamond frame, extended wheel base, and long socket-steering head—the fittest—has survived. A better technical education on the part of bicycle manufacturers and their customers might have saved them a great amount of trouble and expense. Two or three years ago, when there seemed a chance of the dwarf front-driving bicycle coming into popular favour, the same variety in design of frame was to be seen; and even now with tandem bicycles there are many frames on the market which evince on the part of their designers utter ignorance of mechanical science. If the present work is the means of influencing makers, or purchasers, to such an extent as to make the manufacture and sale of such mechanical monstrosities in the future more difficult than it has been in the past, the author will regard his labours as having been entirely successful."

It is merely necessary for any one to go to one of the annual cycle shows and to overhear the, no doubt, honestly attempted explanation of the advantages of some hopeless device, and the apparent satisfaction with which some of these plausible follies are devoured by a section of the public, to feel that Mr. Sharp has expressed himself with too much enthusiasm. Perpetual motion is no more dead now than it ever was; in fact, in consequence of the extraordinary successes in the cycle business during the past year or so, vendors of schemes for creating power are doing a better business than ever. If fifty books as excellent as the one under review were in their hands, these people would always rise superior to the absurd limitations which mere conventional mechanicians recognise.

The real value of Mr. Sharp's book will, in the main, be felt by the manufacturers, who, in many cases, possessed of mechanical instinct, but without sound technical training, are honestly attempting to improve their produce. If any of them is able to handle elementary algebra and geometry, which is all that is asked of the reader, he will be taken in the first portion of the book through a course of instruction in which the principles, so far as they are required for cycle design, of kinematics, statics, dynamics, friction, and the stresses and strains in simple and compound structures are explained in a manner which is admirable. If he is not able to make use of the very elementary mathematical processes employed, he may yet follow much of the reasoning.

The first of the three parts into which the book is divided, is in reality itself an excellent text-book which has the unusual merit that it is not written for students or to meet a syllabus, but simply with the object of enabling any ordinary person with the usual school education to obtain a clear insight into the principles of construction and design. If there is one chapter in this part which will be valued more than others it is the one on bending, in which the theory is explained and then applied to the case of ordinary beams and tubes of various sections The numerical tables in which the sectional areas, weights per foot run, and moduli of bending resistances of solid bars and of steel tubes, should be of use to the designer.

The second part of the book, in which the well-known machines which have taken their part in the evolution of the modern cycle are described, while interesting in many ways, is of decidedly less utility than the first or last, or rather it would be so if it were not fortified by chapters on stability of cycles, steering of cycles, resistance of cycles, and gearing in general.

The third part, which is the largest, is simply one on details; but where there are such a host of details as there are in a bicycle, and each becomes the subject of an essay, the proportion assigned cannot be considered too large. For instance, seventy-two pages are devoted to the frame and to the stresses to which it is subjected Wheels, bearings, chain and other gearing, tyres, pedals, cranks, springs, saddles and brakes are all discussed at length.

Before examining this book more in detail, it may be worth while to say that Mr. Sharp is well known as an ingenious and sound mechanical engineer, so that readers of his book may be well assured that if they come across any statement which seems at variance with their ideas, or with what appears to be common sense, or even with the convictions of racing men, the statement is nevertheless one to be considered carefully.

The chief doubt which occurs to the writer of this review is whether the first 110 pages should have been written at all. This part is, after all, merely a text-book of mechanics, put together, it is true, in such a manner as to give prominence to the problems which a study of the cycle presents, but nevertheless a text-book abstract and black-boardy. If it is desirable that such a text-book should be incorporated in a work on bicycles and tricycles, then no fault is to be found with the substance of it, for it is clear, accurate, and to the point. At p. 110 the all-important question of the stiffness of tubes is reached. This is gone into at some length, both with circular and with other shaped tubes. Some attention has recently been given to the question of D-shaped tubes, which are being employed for the lower back fork of the rear-driven bicycle. The object of making these tubes of D-section

is to obtain the necessary stiffness with a narrow tube, as horizontal space is valuable at this part. Doubt has been expressed by cyclists upon the safety of D tubes when thus used. They will be glad to hear from Mr. Sharp, or to calculate for themselves if they like, as he has shown them how, that the D-tube is stiffer than a round tube of equal width and weight by rather less than 1 per cent. Mr. Sharp, however, advocates the use of tubes of rectangular section for this part of the machine, for they are roughly 33 per cent. stiffer than elliptical tubes of the same depth, breadth and weight.

In the chapter on the strength of materials, a result is given which will surprise those who do not realise the importance of depth in a beam, but who only consider tensile strength and density. Steel is so enormously strong for its weight that, with the exception possibly of some of the new alloys, it is the one material on which the designer of strong and light structures depends. Now in the case of solid beams of the same length, breadth and weight, a light material, such as wood, may be made so enormously deeper than one of steel, that the stiffness which depends upon the cube of the depth actually exceeds that of steel. For this reason a wooden cycle rim is lighter than a solid steel rim of the same width and strength. It probably is not lighter than a hollow steel rim of the same outer shape and weight, any more than a solid wooden beam would be lighter than a compound beam made of steel of the same width, weight and strength in which nearly all the material is at the upper and lower surfaces.

The concluding chapter of Part i. deals with the strength of materials. In this there are two sections of special interest to cyclists. The first relates to the "helical tubing" of the Premier Company. This is an ingenious composite tube made by rolling band steel in a helix, so that at no point has it less than two thicknesses, and then brazing all together. By this method of construction a higher grade of steel can be employed than any used in drawn tubes, and a gain of about 50 per cent obtained in tenacity. This, of course, is at the expense of ductility, so that while a frame built of helical tube will be stiffer for its weight than one of solid drawn tubing, it will, or perhaps it is better to say it should, give way suddenly to accidental stresses which would merely bend an ordinary tube.

The other interesting point is the effect of repeated small stresses of an amount which applied even many hundred times would be quite incapable of damaging a material. Certain parts of a bicycle are subject to alternate stresses in ordinary use, while others are constantly pulled in the same direction. The latter may therefore be made with a somewhat lower factor of safety than the former.

Part ii. is partly historical. This will be welcomed by readers very differently, according to their individual cycling experience. Those who have ridden since the 'seventies, or have followed the progress of the cycle, more especially in the last fifteen years, may turn over these pages with a certain melancholy interest, while those who have only recently joined the ranks of cyclists will probably be tempted by curiosity to learn something about the machines which so recently they despised. In the writer's opinion, the first fifty pages of this part is not likely to seriously interest any one for whom the really new and valuable part of the book has been written.

With Chapter xvii. the valuable portion of Part ii. begins. This is upon the stability of cycles. The author explains the bicycle balance by supposing the rider to steer unconsciously in such a curve that the centrifugal force balances the tendency to overturn. All that can be said of this is that when the rider is following a curved path he must lean over to the angle which every one knows, for this is what may be called the dynamical vertical; but small variations from this have to be counteracted just as much as small variations from the real vertical when a straight path is to be followed. Mr. Sharp speaks of the lateral oscillations that are necessary for stability as being pendular, so that a high bicycle has a slower period than a low. This, no doubt, is true in a way, but the essential difference between a hanging and an inverted pendulum are not pointed out. The former has a natural period—that is, it takes the same time to reach the vertical from any moderate inclination; but the inverse is not the case, an inverted pendulum has no natural time to fall from the vertical to any definite inclination, but only from one inclination to another, and the comparison of the periods between high and low machines can only be made when these inclinations are the same for both. The main point is that there is no natural period for the inverted pendulum, the time becoming greater as the start is made from a truer vertical, and also greater as the angle of fall becomes greater. For this reason it would seem that the more correct view is that the bicycle balance consists in merely running the wheel so as to bring the line of contact with the ground vertically under the centre of gravity, the vertical being the dynamical vertical for the particular speed and average radius of path.

There is one section in this very interesting part which is at variance with the supposed experience and almost universal belief of riders. This is upon the effect of pedal pressure upon side slip. Page 215 rather unnecessarily traces the forces upon the frame and wheel in consequence of pressure upon one pedal. Obviously no sustained pressure by the rider upon the pedal can produce a lateral force upon the tyres, however much riders may think the contrary; but is it not possible that this lateral force may exist, and to a more than perceptible extent, in consequence of the fact that it need not be sustained, that it is not one of the entirely balanced internal forces, but is unbalanced, the lateral momentum of the rider's body supplying the force which is external to the frame? This depends for its possibility upon its not being sustained, for if it were the rider would move laterally off the machine; as it is he begins to acquire a lateral velocity, which is pulled up and reversed at the next half-turn. This is the lateral equivalent of the objectionable vertical swaying of the body, which enables the rider to exert an effort on the pedal greater at the time that it is useful than that which the vertical force due to his mere weight would allow. In the middle of the stroke the vertical acceleration of the body is made a maximum, and so the position is at its lowest. At this time, therefore, a greater pressure is available; at the ends of the stroke, where pressure is less useful, less is applied, and gravity is

occupied in stopping the rise and starting a fall of the body. Thus the rider is able to store up the effect of gravity at the less useful, and employ it at the more useful periods, and so relieve his arms from the holding-down strain, which is so tiring.

After dealing with other points in connection with stability, the author comes on to steering in general, and to the difficult subject of steering and balancing upon the "Rover" type of safety without using the hands. Five pages of somewhat difficult reasoning are devoted to this point, and after the establishment of all the forces and couples which come into play, a theory is elaborated which should apply even to the case when the steering axis cuts the ground at the point of contact of the front wheel. It is often stated that riding without hands under these conditions is impossible; difficult it is certain to be, for this feat, as it used to be considered, is certainly easier when the castor action is moderately increased. It would be interesting if expert cyclists who have the means would see if they can succeed.

The writer noticed, when first practising to ride without hands, that the lateral hinging of the body about a joint in the neighbourhood of the saddle seemed to have a definite influence. This motion is evidently under the control of the rider, and so an actual variation of inclination can be forced upon the machine, the amount relatively to that in the upper part of the rider's body depending upon the moments of inertia of the two systems about their independent horizontal fore and aft axes. By this means it is certainly possible to make a rapid and temporary inclination of the frame, which, combined with the gyroscopic action of the front wheel, is all that is needed to control the steering. No doubt the forces calculated by Mr. Sharp act as he has explained, but to what extent they, or the temporary dynamical action just described, are those which are depended upon in practice, whether consciously or not, the writer is not prepared to say.

The chapter on resistance of cycles is very instructive. The conclusions are represented graphically, so that any one non-algebraically-minded can grasp the enormous importance of air resistance at high speeds. Extrapolating from these curves, it is seen that a man who can drive his machine under present conditions through the air at, say, 30 miles an hour, would, if road and machine resistance only had to be met, be able to drive at 330 miles an hour, or if he can actually go 20 miles an hour, he would be able to drive his machine 100 miles an hour. This shows the very essential part that pace-making plays in the cycle race. Whether Dr. Turner's theory on the fatigue caused by brain work in constantly determining the most suitable speed, plays any part or not, it is evident that a long machine with half a dozen riders upon it, or an autocar just in front of the racer, will make such a draught as materially to reduce the enormous resistance he would meet with if the air were still. The writer would like to propose a method to enable great speeds to be attained, which, however, is of spurious interest, since in real cycling the wind resistance must be overcome. All that is necessary is that a large box or small house with glass sides big enough to entirely surround the rider, but with a safe margin, should be dragged by steam or other power along at gradually increasing speeds until the rider shows that he is beginning to lag. Of course, there would be no floor or bottom to the box, and it should be made so that it would clear the ground by any predetermined amount. It might be safer if the house had no back.

Another suggestion offered more seriously where record-breaking without pace-making is the object, is that a day should be chosen when the barometer is very low, for a fall of an inch, if it reduced the air resistance by one-thirtieth, might mean a gain of a second in a minute, or a minute in an hour, *i.e.* if the corresponding diminution of oxygen in the rider's lungs did not compensate for the reduced resistance.

The chapter on gearing is one that cycle inventors would do well to study. It is interesting here to find the Simpson lever chain under the heading "Perpetual Motion." Mr. Sharp very clearly and forcibly points out the fallacy that renders auxiliary hand-power mechanism a practical failure.

Part iii. opens with two chapters upon the frame, which will probably be found to designers the most useful in the whole book. Graphic methods, explained in the first part, are employed to show how the stresses in a link-work frame can be calculated. It is clearly important that the design should be such in a cycle frame, that the members of the frame may be mostly in tension or compression, as they would be if they were pivoted and not brazed together. The difficulty of dealing with the actual case in practice in which they are brazed, and stresses other than tension and compression are certainly met with, is only referred to, but, perhaps wisely, the anxious engineer is not shown how to reduce these to figures.

It is a question whether too much stress has not been laid upon the necessity of straight members in a cycle frame, for in order to meet the racking and other stresses which must be met with in practice, a gauge of tube is necessarily employed, which, considering the frame as a mere girder carrying a dead weight, is quite absurdly strong, so that a moderate bending moment, due to the design, need not be feared when some distinct gain is effected in consequence.

This is more especially the case in the dropped frame which, unfortunately for themselves, ladies in this country think they prefer. Great abuse is often heaped upon the makers of machines with curved frames. Now, provided that the top and bottom members are kept apart, and the more so the better, and are effectively stayed at a few points, the bending stresses introduced by the curvature are quite moderate, and space is obtained where it is required, so that mounting and dismounting is more easy A further point is the extra steepness of the frame in front, which allows the skirt to hang more easily.

Mr. Sharp accepts the situation with regard to ladies' machines as he finds it at the present day in this country. Again, perhaps, he is wise. He assumes a drop frame to be a necessity. Now, if any person will depend upon reasoning alone, and pay no attention to the vagaries of fashion, he will see first, as is evident from Mr. Sharp's diagram, that the stresses in a so-called lady's "Safety" are greater than in one of proper design, so that in order to make it strong and stiff enough the machine has to be heavier than any that a man would ride, and is even then without that wonderful rigidity of the diamond frame.

Add to this the fact that the fair sex have not the strength or any of that recuperative power necessary in case of emergency that man possesses, and that they suffer many fold from the ever-disturbing wind resistance in consequence of the garments which fashion imposes upon them, and that because of these same garments they are in sorry plight in case of a moderate accident; with all this in the mind of a mere reasoning person, there is no wonder that he thinks of something else, the degree question at Cambridge for instance. Had the suburban ladies been given another year or so before the desire to ride a bicycle extended so far in the direction which is known from a mere social point of view as upward, it is possible that the change of attire would have spread gradually, and that now, or perhaps in a year or two, suitable costume would have been adopted as readily as the cycle jargon and slang so often met with. Ladies start with every natural disadvantage, and then they proceed to magnify them in a more effective way than their conscious ingenuity could devise.

The chapter on wheels is one which will be read with interest by riders especially. Here will be found a description of the author's tangent wheel, in which the spokes are not fastened to the hub at all! It is almost impossible to believe at first that spokes held in pairs to the hub by merely having their common centre portion wound a fraction of a turn round the hub will hold sufficiently tight to withstand all the twist that a strong rider can exert upon them. But the theory is convincing, and especially when steep-angled grooves are employed in which to lay the wire, no doubt can remain that this is the case.

Ball-bearings form the next subject, and these are treated far more thoroughly and scientifically than is usual. The actual want of absolute perfection in the ordinary bearing is pointed out, and a number of suggestions made for bearings in which the balls approach as near as possible to the state of pure rolling. The ordinary ball-bearing answers so well, in spite of the spinning and rubbing friction which accompanies the rolling, that it is hardly likely that the more elaborate bearings, in which these defects are reduced or abolished, will take their place. At the same time, a discussion of them is of educational value to designers.

Chains and chain-gearing are dealt with very thoroughly and completely. There is one omission, however, which must be noticed, and that is all reference to the results of Hans Renold, of Manchester, who found that a small difference of pitch is desirable in the driving and driven wheel. The writer of this notice picked up one of Renold's pamphlets at a cycle show some years ago, and was much struck with the arguments there used. It may be that this is all common knowledge, or that it is mistaken; but either way, one would like to have had Mr. Sharp's views upon the subject.

Mr. Sharp explains the correct method to setting out chain wheels for long-link and for block chains; he is not afraid of criticising one of the chief companies.

"In Humber pattern chain-wheels the teeth are often quite straight (Fig. 451). This tooth form is radically wrong."

On page 417, Mr. Sharp points out a defect in a usual pattern of chain which the practical man would hardly expect. Here the plates of the chain are cut away on the side next the chain-wheel, so that the line joining the rivets is not in the middle of the portion that is left. If the plates were cut away on the other side as well, so as to leave less metal, they would be stronger still. In the next page there is a suggestion which seems valuable, namely, to make the side plates of metal which has been stretched beyond its elastic limit, and which therefore has an increased rigidity. As these links can never be subjected to compression, the objection to this procedure, which is met with in other cases—as, for instance, in Southard's twisted cranks—does not apply.

The bicycle chain is a more marvellous piece of mechanism than is generally supposed. The pins have to bear a force which is far greater than is prudent in ordinary structures, while the bearing surface of the blocks on the rivets have in use occasionally to bear more than twice the amount given by Prof. Unwin as the maximum value for bearings on which the load is intermittent and the speed slow.

The discussion on the variation of relative speed in the driving and driven wheel is curious rather than important.

One result of the rules given by Mr. Sharp for shaping the teeth of sprocket wheels is that even in elliptical wheels the teeth will have the same form as in circular wheels of any size, so that the same cutters can be employed for all wheels if adapted to the tooth face, and not made simply to plough out the space between two teeth at one cut.

The practical reader would like to know whether the tooth forms recommended work well in practice, for there is undoubtedly much prejudice in favour of the patterns of our standard makers, whether condemned by Mr. Sharp or not.

Toothed-gear wheels are treated at length. The theory is, of course, common knowledge, but it is very well put, and the results of a paper on circular-wheel teeth, published by the author in the *Proceedings* of the Institution of Civil Engineers, are given also. Toothed-wheel gears follow. The mechanical reader who is not already acquainted with these, will be surprised at the ingenuity and perfection which are embodied in this class of work.

There is much remaining unnoticed, but the length to which this review has reached is such that many interesting points cannot be even mentioned.

"Bicycles and Tricycles," by Sharp, has taken its place as the one standard book which ought to be found wherever cyclists do congregate, and which no one designing or inventing any detail connected with a bicycle should fail to possess. C. V. BOYS.

THE GEOLOGY OF THE BRITISH ISLES.

Geological Map of the British Isles. Originally compiled by Sir Archibald Geikie, LL.D. Revised and extended by Alexander Johnstone, F.G.S. (Edinburgh and London: W. and A. K. Johnston, 1896.)

Mineralogical Geology: a Synopsis for the Use of Students. To accompany W. and A. K. Johnston's Geological Map of the British Isles. By Alexander Johnstone, F.G.S. (Same publishers as above, 1897.)

THE first of these works is by a long way the best and most convenient geological map of the British Isles, both for lecturers and students; and this new and greatly

revised edition has added considerably to its utility. It is, indeed, not likely to have a serious rival until the completion of the index-maps of the Geological Survey; and these will still be on too large a scale for the purposes of a comprehensive view. On the present map, fourteen miles go to an inch; and we are glad to see that a scale of kilometres is added. The colouring is clear and bold; and a number of small-type notes along the coast call attention to local details, as is customary in British maps of an educational character.

A series of well-chosen longitudinal sections occupies the blank spaces in the surrounding seas. It would be an advantage, in the next edition, to be informed as to the length of each section in miles, since some are naturally of a much more general character than others. In one, moreover, the term "Neocomian" is used, though it does not occur in the Table of Systems which forms the index. In another, owing, probably, to the small scale, there is a striking unconformity between the London Clay and the Bagshot Beds of the London basin. Teachers will be glad to have the Erriboll section, as an example of the northern thrust-planes; and the whole series will prove of constant service.

In the index, we note with pleasure the use of "Stonesfield Flag"—an "s" is probably omitted—for the well-known but misleading "Stonesfield Slate." In the Pre-cambrian group, the Caledonian Schists, the Hebridean, and the Dalradian, are separately coloured; and it is here that the map is in course of time likely to undergo modification. It has had the advantage of following Sir A. Geikie's recent edition of his map of Scotland, and is naturally a great improvement on other available wall-maps, in which all the schists east of the Torridonian border are classed and coloured as Ordovician. Ireland receives similar treatment; but here again some reminder is required of the prudent and cautious language with which the term "Dalradian" was introduced to geologists by its author. The Ordovician areas of eastern Ireland are also likely to become broken up, through the discovery, now announced, of several Silurian districts in their midst.

In South Wales we have a doubtful boundary, a dotted line, drawn between Silurian and Ordovician; and in many other of the older areas the map draws attention to recent observations. Even the Lenham Beds receive proper recognition along the scarp of the North Downs.

In trying to separate the Old Red Sandstone of southern Ireland into an upper and a lower division, Mr. Johnstone has naturally fallen into the common pitfall. As a matter of fact, the Dingle promontory and the region south of Omagh are the only safe areas where the Lower Old Red Sandstone can be marked out. Prof. Hull drew a provisional line across the centre of the county of Cork, which Mr. Johnstone properly puts aside, as being merely a suggestion. But he carries his Lower Old Red Sandstone along the south of the Blackwater, and colours the same rocks, where they emerge on the north side of the synclinal, as Upper Old Red Sandstone. The logical thing seems to be to use one tint at present for the main Irish Old Red Sandstone, and to split it into two minor tints for the benefit of the Dingle and Tyrone areas.

A few misprints require revision in the notes along the coast, such as "roches montonées," "Permiam," and "Greenstones" for the town Greystones. There are two references to Eocene plant-beds at Portree, but none at Ardtun, although the unimportant tachylyte at the latter point is mentioned. When we find, however, Radiolarian cherts and the Dover coal among the recent additions to our information on the map, we are not inclined to point out small omissions. We may rather end, as we began, by recommending schools, teachers, and public institutions to place this clear and conscientious work, without delay, by the side of any older general map which they may happen at present to depend on.

The earlier edition of Sir A. Geikie's map was accompanied by a concise handbook dealing with the geological structure of the British Isles. Some such book is obviously desirable, and the new map has provided an excellent opportunity. The progress of our views regarding the relations of certain strata could have been pointed out, and the meaning of such terms as "Dalradian," "Ordovician," &c., could have been made clear. There was ample room for a picturesque and yet accurate description of the features recorded in the map itself, prominence being given to those aspects of the country that would strike the ordinary traveller.

In what sense, however, Mr. Johnstone's tabular treatment of elementary mineralogy "accompanies" the map of the British Isles is indeed hard to discover. The author has given excellent and judicious prominence to the localities in which the several minerals occur in the British Isles; and a series of plates of British fossils occurs as an appendix, repeated, if we mistake not, from the borders of the original map. The revision of the names on these plates still remains to be done; we have "Fenestalla," "Rhynconella" more than once, "incrasata," "Cyrene," and divers similar slips. One Eocene mammal is even labelled "Palæo magnum." Our old friend, the seated Pterodactyl, still appears with his five digits on the hand. However, it may be justly urged that these illustrations have nothing to do with the book under review, which is an introduction to the study of minerals. As a book of reference for well-taught students, it may have its value; and we suspect that it has been compiled from notes already found useful by the author in his own courses of instruction. But it suffers from somewhat imperfect proof-reading, as in the case of the formulæ of the felspars on page 7; the mica formulæ also surely require revision. Where, moreover, are "Pary's Mine," "Magee Island," "Penmaen Maur," "Corinthia," and a few others?

We confess to feeling afraid of a small work so full of facts and figures; but its compilation must have involved serious work. The subject is plunged into abruptly, as when we are told in a foot-note on page 11 that "a growing together of two or more crystals constitutes a macle or twin." It is satisfactory to find a fuller treatment of twin-crystals on page 45; but the beginner is then informed that "when chemically and physically similar crystals at an early phase of their existence unite at inversely dissimilar parts to form a compound crystalline body, the product is called a twin macle, or hemitrope. . . . The plane of junction (*plane of composition*) is throughout the *twinning plane* in young

forms." This makes us truly wish for a teacher at our elbow. The difference between young and old twins is new to us; the Carlsbad twins, by the above statement, were clearly never young.

Altogether, this book must be compared with our smaller treatises on mineralogy, and must be judged accordingly. As a reference-book for British localities of minerals and rocks it will undoubtedly be useful.

G. A. J. C.

OUR BOOK SHELF.

A Ride through Western Asia. By Clive Bigham. With illustrations. Pp. 276. (London: Macmillan and Co., Ltd., 1897.)

MR. BIGHAM gives a simple, straightforward and modest account of a journey of the "record-breaking" order. In a year and a month he travelled, mainly on horseback, from Constantinople through Asia Minor, Persia and Central Asia, reaching as far as Kashgar, thence returning *viâ* Siberia and Russia. The small size of the book is welcome, and indeed remarkable, as it shows that the author cherishes no undue opinion of his somewhat remarkable journey. It is to be regretted, however, that his duties as a correspondent at the seat of war deprived the proof-sheets of his personal revision, and that many slips, chiefly in place-names, have thus eluded observation. Mr. Bigham was possessed of the best qualities of an explorer determined to go through a given programme; but he does not mention the special object for his expedition, nor does he tell much which had not previously been placed on record. The object presumably was merely pleasure, and the points of original importance refer to matters of undoubted interest, but so intimately involving political questions as to be unsuited for special reference here.

Numerous quotations are given from Mandeville, Marco Polo, the Vulgate and other authorities, and the author assumes as matters of common acceptance several theories, anthropological and otherwise, which are either exploded, or are now looked upon with great suspicion by competent authorities. Perhaps the most interesting part of the journey was the trip from Teheran through Kashan, Ispahan, Shiraz, and across the Bakhtiari country to Dizful, down the Karun River, up the Tigris, and back to Teheran by Kermanshah and Hamadan. It is a pity that fuller details of the Bakhtiari country were not given. The same may also be said of the journey from Kashgar to Semipalatinsk, across the Tian-shan, so early in the year as the month of May. There was too much travelling compressed into the thirteen months to allow of the careful collection of local information, which might be of scientific value; but the book is attractively written with plenty of action, maps well suited to bring out the routes, and good illustrations.

Elements of Theoretical Physics. By Dr. C. Christiansen, Professor of Physics in the University of Copenhagen. Translated by W. F. Magie, Ph.D., Professor of Physics in Princeton University. Pp. xii + 339. (London: Macmillan and Co., Ltd., 1897.)

WHILE the small edition of Thomson and Tait's "Natural Philosophy" professed to supply the essential details of this reasoning, devoid of mathematical notation, the present treatise appears to perform the converse operation, of providing the student of Physics with the mathematical argument and equations he is likely to encounter, devoid of any appeals to experiment or numerical illustration. The book is therefore a very handy manual of reference for formulas, and the mathematical treatment is very elegant and condensed, not running to unnecessary luxuriance. As it is stated at the outset that the C.G.S. system alone is employed, there is no need for any specification of the units employed; although we think it would tend to clearness to mention them occasionally; and this can be done, on the Hospitalier System, in a very condensed form, thereby training the student not to shirk this most important detail of his practical work; thus, for instance, the number $1{\cdot}695 \times 10^{12}$, representing the modulus of elasticity on p. 81, is given in dynes/cm^2.

The subjects treated in the chapters are—General Theory of Motion, Theory of Elasticity, Equilibrium of Fluids, Motion of Fluids, Internal Friction, Capillarity, Electrostatics, Magnetism, Electro-Magnetism, Induction, Electrical Oscillations, Light, Thermodynamics, and Conduction of Heat. These subjects are all polished off in 333 pages; and as most of them are discussed ordinarily in separate treatises, each of, say, 300 pages to itself, the treatment in this work is necessarily very condensed, and the author cannot permit himself any following out of details, or Calculus dodging.

This will make the book a difficult one for a beginner to use, except as a handbook of reference, to be used in conjunction with a series of Lectures; and it was probably in that way that the treatise assumed its present shape.

G.

In Garden, Orchard and Spinney. By Phil Robinson. Pp. iv + 287. (London: Isbister and Co., Ltd., 1897.)

The Woodland Life. By Edward Thomas. Pp. viii + 234. (Edinburgh and London: Blackwood and Sons, 1897.)

THE critic to whom these volumes were entrusted read a good part of them with a growing sense of perplexity not unmixed with enjoyment. When he attempted to write down what he had found in them, he could for a long time do nothing but gnaw his pen. At last it occurred to him that almost any reader of NATURE would have found himself in a like difficulty, and that the best plan would be to speak of the books from his and their point of view. We, the readers of NATURE, are accustomed to read for information, and we judge of books mainly by the quantity and quality of the matter which they contain. Now the two books before us may be shortly said to contain no information at all; to give information is no part of their plan. They are akin to the sonnet, the symphony, and the landscape painting, and make their appeal to sympathies of which the mere naturalist is quite devoid. Even the dull soul of the mere naturalist is, however, faintly stirred now and then, as he reads these pages, wondering all the time what he can find to say about them. Mr. Phil Robinson throws in many a pleasant phrase, many an apt quotation, and there is plenty of movement in his descriptions. Mr. Thomas' touch is not so light, but among his abundant epithets are not a few which show real familiarity with the natural objects, especially the birds, which catch his eye. Though these books make no pretence of being founded on inquiry, nor of adding to knowledge in any way, it is quite possible that a competent judge of literary form would give them a good place as prose poems.

L. C. M.

Social Transformations of the Victorian Age. By T. H. S. Escott. Pp. viii + 450. (London: Seeley and Co., Ltd., 1897.)

THIS book calls for but a brief reference in these columns. It consists of a series of sketches of social and legislative changes which have taken place during the Victorian era, and points to some of the causes of these transformations. Education receives a fair share of attention, but the transforming influences of science occupy only a single chapter of sixteen pages.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Colour Photography.

I HAVE had a good many inquiries addressed to me about the Dansac-Chassagne process of colour photography, described in NATURE, February 4, 1897, and as I was to a large extent responsible for having drawn public attention in this country to the process, I am naturally anxious that those who feel an interest in the subject should have, at all events, such information about it as I can supply without a breach of the confidence with which I have been favoured.

First let me say that the information I can publish does not include any details as to the materials employed, or the method of their manufacture. The process is to be worked as a secret one, and the statements made to me as to the method of preparing the liquids used were confidential. This of course greatly affects the scientific interest of the question, but commercial considerations in this, as in many like cases, overpower scientific interest.

It is only quite lately that I have been able to make any fuller examination of the process, and such rough tests as I have made are very incomplete. They are, however, complete enough for me to say that, while they do not justify the claims originally put forward as to the completely automatic nature of the process, I yet cannot account for the results produced without admitting that the selective action claimed does to some extent exist; that the colouring matters applied to the photographic print have a certain tendency to attach themselves to those portions of the print which would be of a similar colour had the image been reproduced in natural colours, and also that the colouring matters, when applied in succession, do so combine or react on each other as to reproduce, approximately, the tones or tints of the original.

There are some other inaccuracies in the first description given to me, which I should like to correct. It does not appear to me that a special negative, or a special print, is any advantage. It certainly is not necessary. The process can be applied to any ordinary print on albumenised paper, or to any positive on an ordinary gelatine plate. It does not appear to work successfully with some, at all events, of the more modern printing-out papers. Nor is it a fact that during the process of treatment the positive has to be exposed to bright light.

This it will be said is different from the process as it was first described. Precisely. It is because of that difference, and because I was responsible for the publication of the first description, that I now ask you to allow me to inform your readers as to the real value of the process so far as I can estimate it at present.

The above conclusions are based on my own attempts, and some rather more successful) by my friend Mr. Herbert Jackson. Judging from the work of the skilled operators, whom I have watched in M. Chassagne's studio, I can only say that in their hands the process is certainly not entirely automatic. The operator requires to know generally what the colours should be, and the results largely depend on his judgment and skill in applying the colour in the right places.

But the practical outcome is that anybody, after a little instruction, can produce, with very great rapidity, coloured pictures which, as evidenced by the specimens shown in public, are of considerable merit. The result is obtained by first applying the liquids over the whole picture, and then working up the different parts of the picture by applying them locally. About the truth of this there can be no manner of doubt. Hundreds of persons in Paris have seen it done, and have admired the results. The difficulty is to satisfy oneself as to how far the process is purely mechanical, and how far it is a matter of skill. A certain amount of skill is required, but, admitting this, it appears to me that taking it at its lowest value, the process does provide a means of colouring photographs—and with approximate correctness—that has not previously been available.

Whatever may be the practical or commercial value of the process, it will prove of very great theoretical interest, if as an outcome it should be conclusively proved that any monochrome photograph has even the smallest power of colour selection, depending on the tints of the original; as this once established, some of our current photographic notions would be revolutionised.

HENRY TRUEMAN WOOD.

Telegraphy without Wires, and Thunder-storms.

I HAVE recently made experiments on telegraphy without wires, and during the last few days, which have been very hot, I have experienced certain phenomena which somewhat interfere with the reception of signals. The receiver used by me is constructed thus: a piece of goose-quill one inch long is stopped at each end with cork, two ordinary pins pierce each cork, their points being about $\frac{1}{8}$-inch apart; the intermediate space is filled with finely-powdered nickel; (experiments on the relative sensitiveness of receivers made with quill and glass show that those made with quill are more sensitive than those made with glass.) The receiver is attached to an acoustic resonator carrying an electrically driven tuning-fork (500 double vibrations per second). The receiver is placed in contact with the foot of the fork, where it is attached to the resonator. The receiver forms part of a circuit including a dead-beat galvanometer, a single dry cell, and a resistance of 1500 ohms. One terminal of the receiver is earthed, and the other is attached to a thick copper wire, 30 feet long, fixed to a post. The vibrating fork effectually maintains the high resistance of the receiver, except when it is affected by a spark at a distance. The galvanometer is then instantly deflected, but at once returns to a nearly zero position. While I was watching the spot of light of the galvanometer, I noticed that it was deflected when the transmitter was not in action; after some time distant thunder was heard; in some cases the time between seeing a deflection and hearing thunder was 25 seconds, a time corresponding to about 5 miles; by degrees the storm, though at some distance, caused the spot of light to be deflected up to 25 times per minute.

From what I noticed it is evident that signalling would be somewhat seriously interfered with by a thunder-storm even at a considerable distance.

I have used the tuning-fork method of shaking the receiver since last February, and have never seen it fail in its action. Another method which gives good results is to mount the receiver on a small projection cemented to the disc of a telephone, in the circuit of which an electrically driven tuning-fork and a battery are included.

June 26. FREDERICK J. JERVIS-SMITH.

Distant Cannonade.

IN answer to your note upon the distances at which Saturday's salute was heard (NATURE, July 1, p. 204), I have to say that I heard what I suppose was the salute here in Chelsea. I took it at first for distant thunder, and went to look at the sky and barometers.

The newspaper reports showed, since that, that the thunder-storm was much later; and I did not hear sounds of it at all. The sound reminded me rather of a *feu de joie* than of a salute, which is accounted for by the fact that the squadrons saluted in succession.

There is nothing unusual in the hearing of artillery at such a distance, about sixty statute miles. The Bombay time guns and salutes are often heard at the northern Mahim, a known distance of over fifty statute miles. They are, or were in my day, very modest affairs—old-fashioned twenty-four or thirty-two-pounder guns, loaded with four or five pounds of coarse black powder, not all of which was burnt. I was working at warning guns in that country myself for some years, and had to attend to such matters, but have no notes here from which I can give exact figures.

The target practice of the forts and turret-ships at Bombay was very easily distinguishable from mere salutes and time guns; not merely as a louder sound, but by being *felt* in the chest when those could only be heard. Probably some of your naval readers can tell us something of the guns and charges used at Spithead on June 26. It may be presumed that they were of more power than the old-fashioned artillery that I have mentioned; but still it is probable that they were the smallest guns of the fleet, and the saluting charges much less than those for service. The sound produced by modern powders, too, is probably very different in quality from that of the old black powder with which the late Prof. Tyndall made his experiments.

The subject is of very considerable importance, and any information that our "up-to-date" gunners can give us will be welcomed by all connected with the sea.

102 Cheyne Walk, Chelsea. W. F. SINCLAIR.

Rotifers Commensal with Caddis-worms.

IT may be of interest to record the fact that, like *Gammarus pulex* and *Asellus aquaticus*, the larva of *Phryganea grandis* is a host for the commensal rotifer, *Callidina parasitica*. On one specimen, taken near Potter Heigham Bridge, I found between fifty and sixty of these commensals. As is the case with the commensals of *Gammarus* and *Asellus*, those of the caddis-worm gradually disappear when the hosts are kept in an aquarium. *Rotifer tardus* was also found among the materials of the larval case. HENRY SCHERREN.

The Lost Books of Euclid.

WILL you or any of your numerous readers kindly let me know, through the medium of your journal, if the lost books of Euclid (Books vii., viii., ix. and x.) have been found and published in English; if so, the name of the editor and that of the publishing house.

I may say, in reference to this inquiry, that an Indian Prince, who is at present in this country for the Jubilee celebration, possesses a complete copy of Euclid in Sanskrit—no book or books missing. A. K. GHOSE.

6 Forest Road, Kew, June 8.

[WE are indebted to Mr. H. M. Taylor for the following information:—

The first English translation of the Elements, published at London in 1570, had the title (16 Books):—

"The Elements of Geometrie of the most ancient Philosopher Euclide of Megara, Faithfully (now first) translated into the Englishe toung by H. Billingsley, City of London. Whereunto are annexed certain Scholias, Annotations and Inventions of the best Mathematicians both of time past and in this our age."

The English edition of the first printed Greek text, published at Basel, contained all the extant works attributed to Euclid. This was published in 1703, at Oxford, by Dr. David Gregory, and was entitled "Εὐκλείδου τὰ σωζομένα."

See Encl. Brit., ninth edition, for further information.—EDITOR.]

ARCHAIC MAYA INSCRIPTIONS.

THERE can be no surer sign of the smallness of the number of persons in this country who take an interest in the progress of our knowledge of American archæology, than the fact that not many years ago the editor of this journal asked me to review my own work on the subject, a request which, as far as courtesy would allow, I succeeded in avoiding by effecting a compromise which resulted in the publication of a few general notes on the ancient civilisation of Central America (NATURE, April 28, 1892). The far more grateful task has now been entrusted to me of calling the attention of the readers of this journal to an essay on the Archaic Maya Inscriptions, by Mr. J. T. Goodman, of California, which has been published as an appendix to the archæological section of the "Biologia Centrali Americana."

It is to the liberality and sympathetic kindness of Mr. F. du Cane Godman and Mr. Osbert Salvin that my work on Central American antiquities is being published in its present sumptuous form. Their names, indeed, figure on the title-page as editors; but the old-fashioned and much abused title of patrons would be more appropriate in expressing an ideal relationship in which they have confined their editorial duties to giving the kindliest and most valuable advice, whilst leaving me an absolutely free hand in the selection of material, and relieving me of all expense of printing and publication, and the reproduction of photographs, plans and drawings, which already extend over 175 double quarto plates.

It is again to this same liberality that my friend Mr. Goodman's interesting essay owes its publication; and were he here I know how heartily he would join me, and I think I may add so would every other student of American archæology, in a grateful acknowledgment of the deep debt of gratitude we owe to the editors of the "Biologia." To Mr. Goodman, as to myself, has been accorded an unrestricted freedom in the expression of his views; and after fully acknowledging the assistance he has received on this side of the water, there are passages in the preface to his essay which may be taken to express a natural disappointment that the value of his work was not recognised, and its publication ensured in the land which he loves so well.

Such attempts as have previously been made to interpret American hieroglyphic inscriptions have been mainly directed towards the interpretation of the three or four Maya manuscripts or codices which alone have escaped destruction. Although Mr. Goodman has not failed to devote the most careful attention to that branch of the subject, giving years of study to the codices as well as to the Yucatec and Cachiquel Calendar systems, it is to the interpretation of what he terms the "Archaic system," that is to say, the system of notation employed in the carved inscriptions found amongst the ruins of Palenque, Copan, Quirigua, Menché and Tikal—an almost untrodden field of research—that the present essay is devoted.

It will doubtless be disappointing to the general reader to learn that the greater part of the carved Maya inscriptions deal only with dates and the computation of intervals of time; but this is a fact which has gradually been forcing itself on the minds of students.

As Mr. Goodman says:—

"It may appear absurd, at first thought, that temples, monuments and altars should be covered with elaborately carved inscriptions that record nothing but dates and other forms of time reckoning. But a little reflection should convince one that such inscriptions, under certain conditions, would not be preposterous, but the wisest and most useful of records. A calendar is an indispensable requisite of civilisation. The very attempt to construct one is the first step towards evolution from savagery, and a completed calendar of any kind is proof that the transition has been accomplished."

The work of constructing a satisfactory calendar system from the chaotic fragments of information which have come down to us, has been a work necessitating the most extraordinary patience and insight. Not only must such a system stand the test of application to the inscriptions which are already known, but it must be prepared to stand the further tests to which it will be continually submitted as hitherto undiscovered inscriptions are brought to light.

Of the methods employed by Mr. Goodman in the preparation of his calendar a slight sketch is given us, and he tells us how it was to the writings of Diego di Landa (A.D. 1566), the Bishop of Yucatan and arch-destroyer of Maya records, that he had finally to return as his only trustworthy guide.

It is impossible in a short notice even to touch on the numerous points which had to be considered in the preparation of the calendar tables which accompany Mr. Goodman's essay. The main factor is the concurrent use of two systems based, one on a year of 360 days, and the other on a year of 365 days.

The Chronological Calendar deals with the former system, the divisions of time being

20 days	1 Chuen.
18 Chuens	1 Ahau (360 days).
20 Ahaus	1 Katun.
20 Katuns	1 Cycle.

13 Cycles = 1 Great Cycle.

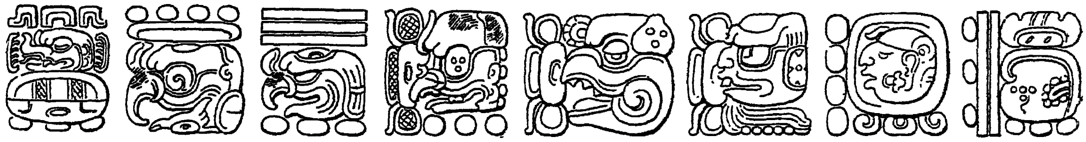
It is somewhat unfortunate that the Ahau, or period of 360 days, bears the same name as one of the twenty days of the Maya month, and in the same manner that the Chuen, or twenty-day period, is made to bear the name of another day of the month.

The Annual Calendar is divided into eighteen named

months, each of twenty named days, and one short month named Uayeb, of five days.

This Calendar repeats itself at the end of fifty-two years.

I called attention, some years ago, to the fact that the greater number of the carved inscriptions commenced with easily recognised series of glyphs with numerals or faces attached to them, which I called the Initial Series. Mr. Goodman now shows that the Initial Series expresses a date thus:—



1 2 3 4 5 6 7 8

(1) The Great Cycle sign. (2) The Cycle. (3) The Katun. (4) The Ahau. (5) The Chuen. (6) The Day. (7) The named day. (8) The named month.

As has been long known, each bar counts as five, and each dot as a unit. (The roundish marks *under* the glyphs are not part of the numerical series.)

The signs in front of the Ahau, Chuen and Day signs denote a "full count" of those periods. The date thus reads:—

54th	Great Cycle.
9th	Cycle.
15th	Katun.
"Full count"	Ahaus.
"Full count"	Chuens.
"Full count"	Days.
4 Ahau (day).	13 Yax (month).

A reference to Mr. Goodman's chronological Calendar shows that the 15th Katun of the 9th Cycle of the 54th Great Cycle commences with the day 4 Ahau, the 13th day of the month Yax, the date which is here given in the inscription. The combination 4 Ahau 13 Yax can only occur once in a period of fifty-two years.

One of Mr. Goodman's discoveries is the system on which the Mayas numbered the different series of time divisions. For instance, the twenty Ahaus are not numbered 1, 2, 3, &c., up to 20, but they were numbered 20, 1, 2, 3, &c., to 19.

If we should nowadays wish to use a similar notation, we should probably number the series 0, 1, 2, &c., 19; but it seems as though the Mayas, having no sign for 0, wrote the sign for 20 or a "full count" of Ahaus in the first place.

The 18 Chuens are in like manner numbered 18, 1, 2, 3, &c., to 17; the same sign being used for a "full count" of Chuens as is used for a "full count" of Ahaus.

As a "full count" of days (twenty) is a Chuen, a "full count" of Chuens (eighteen) is an Ahau, and a "full count" of Ahaus (twenty) is a Katun. The foregoing inscription may be read thus:—

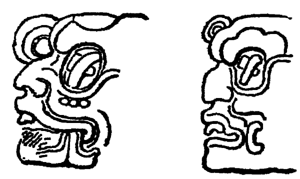
The 15th Katun of the 9th Cycle with no odd Ahaus, Chuens, or days added, begins with 4 Ahau 13 Yax.

Had the date been one including a specified number of Ahaus, Chuens, or Days, we should have had to make use of the Annual Calendar. Without giving examples and tables it is not easy to explain the method employed, which in practice is very simple, and almost invariably gives a satisfactory result; so that we can now locate in the Maya Calendar almost all the initial dates inscribed on the monuments, and many of those expressed in the body of the inscriptions.

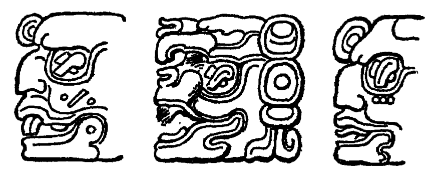
In the first chapters of the essay Mr. Goodman discusses each of the time periods used in the dates and computations, and identifies the glyphs by which they are expressed in the carved inscriptions.

Next follows a chapter on the "Burner Period" (260 days) and the "Bissextile Count," and then a series of chapters on the signs employed to express numbers, in addition to the well-known dot and bar system. The most interesting of these chapters is that devoted to the "Face Numerals," in which it is shown that the face so frequently met with in the inscriptions in connection with Cycle, Katun, and other signs for time periods, are in reality numerals, and the whole series of numeric faces from 1 to 20 is determined in some cases with certainty, and in others with a fair degree of probability.

The "face sign" for 10 is a death's-head, and it is interesting to note that some of the faces representing numbers from 10 to 20 are repetitions of the faces representing numbers from 1 to 10, with the addition of a death's-head jaw, or some other similar combination of 10 and the lesser numeral. Thus 6 is expressed by a grotesque face with a hafted stone axe in the eye.



And 16 is expressed thus—



the death's-head jaw replacing the more natural form of a jaw.

With the remaining chapters of this essay it is impossible to deal within the limits of this article; although the student may not always be able to agree with the conclusions arrived at, he will find an abundance of helpful suggestions. A table of signs is given which denote "the beginning"; numerous "directive" signs are distinguished, such as those indicating a reckoning "from the beginning of a cycle" "from the preceding date," &c., as well as "declarative" signs, such as "the beginning of a Katun," &c.

Then follow "Exercises in Decipherment" and "A Review of the Inscriptions"—that is, of those inscriptions of which drawings have already been published in the "Biologia Centrali Americana," and some others now in course of publication.

The essay is accompanied by a "working chart" in which the equivalent of each of the different time periods is given in days, and by a "Perpetual Chronological

Calendar"; also by a complete "Annual Calendar" for each of the fifty-two years of the Calendar round, and a complete "Chronological Calendar" for three great cycles. In these three great cycles all the dates as yet found in the inscriptions can be located; and, according to Mr. Goodman's theory of a Grand Era of seventy-three great cycles, these three great cycles are numbered the 53rd, 54th and 55th.

No doubt the first objection raised to the scheme will be the improbability of the Mayas having had a chronological system extending over 374,400 years, the number of years composing a Grand Era. And the objection will have all the more force, in that no such time period is mentioned by Landa or any other authority. Mr. Goodman says the Grand Era is a necessity to round off the various time periods on which the Mayas rested their computations. It does not appear to me that this would of itself necessitate a phenomenal antiquity for Maya civilisation, for the Mayas, like every other race, must have been confronted by the question, "When did time begin?" We ourselves have avoided the difficulty by taking a certain point of time, and reckoning forwards from it and backwards until we are lost in the mists of antiquity; but it must be remembered that it is only in the last few years that the date 4004 B.C. has disappeared as a marginal note from the first chapter of Genesis. Is it, therefore, impossible to believe that a people may have reckoned backwards to an imaginary beginning of time, fixed by a purely arithmetical calculation as the point when all the complicated time periods with which they were in the habit of reckoning could have started fair? How those time periods became so complicated, and needed such a vast stretch of time to work themselves out, is another matter—possibly it may have originated from the combination of various methods of reckoning time employed by different branches of the race. However, I must not start theorising on my own account, but refer the reader to the chapter on the "Era and Duration of the Archaic Maya Civilisation," where Mr. Goodman gives reasons for his belief in the great antiquity of Maya civilisation, and shows that between the earliest and latest dates recorded on the sculptures at Palenque there is a difference of 7082 years.

I am so fully aware of my own incompetence to deal with such an abstruse subject as the construction of Calendar systems, that I shall not venture on any critical review of Mr. Goodman's methods or conclusions; but I am glad to have an opportunity of saying that my acquaintance with Mr. Goodman and with his partner in his investigations, Dr. Gustav Eisen, commenced with a correspondence about the drawings of the inscriptions published in the "Biologia Centrali Americana"; and when I was afterwards able again to compare these drawings with the original sculptures, I found that the alterations of form suggested to me with regard to certain obscure and weather-worn minerals and glyphs had nearly always to be confirmed as correct. Then, as Mr. Goodman's methods became more familiar to me, I found myself constantly making use of the results at which he had arrived without any opportunity of acknowledging the source of my information. I was therefore urgent with him to publish the results of his researches, although he lingered fondly over his work, by no means considering it as yet complete.

Since commencing this article a photograph of a carved inscription, lately discovered on the banks of the Rio Usumacinta, has been forwarded to me from Yucatan by Mr. T. Maler. This inscription contains forty-eight glyphs. With the use of Mr. Goodman's tables I am able to locate (in the Maya Calendar) the date expressed in the inscription, and to follow five distinct reckonings to other dates—the reckoning made with the tables giving in every case the same result as that which is expressed in the inscription—and can thus ascertain with certainty the meaning of twenty-two out of the forty-eight glyphs contained in the inscription.

Alfred P. Maudslay.

TWENTY YEARS OF INDIAN METEOROLOGY.

Some years ago, when the Indian Meteorological Service was started, under the directorship of the late Mr. H. F. Blanford, F.R.S., he predicted that the Indian area would yield results second to none in importance in clearing up the mysteries which surround the working of atmospherical conditions. At that time the "Indian Meteorological Memoirs," designed to embody compilations and discussions of data in the spare time of the hard-worked officials of the service, were only just starting.

Six portly volumes of these Memoirs have now been completed since 1876; and, to judge from the character of their contents, and the evident growth of certainty and breadth of view with augmenting experience and improving data, Mr. Blanford's prediction is being fulfilled even more satisfactorily than he could have anticipated.

In 1883 a series of articles, by Mr. Archibald, appeared in Nature, in which vol. i., containing the first twelve Memoirs, were reviewed at some length. Since that date five more volumes have appeared, containing papers by the late Mr. H. F. Blanford, F.R.S., Mr. Hill, of Allahabad, Mr. Frederick Chambers, Mr. John Eliot, F.R.S. (the present head of the department), Mr. Dallas, and Mr. Archibald. In some of these papers the phenomena dealt with, such as hot winds and special storms, are of purely local incidence. In others, conditions outside the Indian area and their variations over a long course of years are discussed. We shall in the present article direct our attention principally to the light thrown upon the latter in the more recent Memoirs. Before doing this, however, allusion must be made to a very important series of papers, which form a large proportion of these volumes, in which the normal diurnal elements are discussed at twenty-five observatories scattered over the entire Indian area.

The adequate presentation of such normals is of vital importance to the efficient work of the Meteorological Department. To estimate an anomaly or abnormal, we must manifestly be able to refer to a correct normal. One of the points early foreseen by Mr. Blanford, and continually insisted upon by his successor, Mr. Eliot, has been the accurate determination of normals for as many stations as possible over the Indian area. At these twenty-five selected observatories, not merely have the normal means been determined, but the diurnal variations in temperature, pressure, wind, cloud, &c., have been worked out most exhaustively with the guiding aid of the harmonic formula, and the critical epochs determined with no stint of labour by the aid of the analytical process known as Jelinek's method of approximation. The series began with Sibsagar, by Mr. Blanford, on June 16, 1882, and was completed by a special monograph on Calcutta, by Mr. Douglas Archibald, in the present year. The area represented by these observatories extends in longitude from Aden to Dhubri in Assam, and in latitude from Leh in Thibet to Trichinopoly in Southern India. Many valuable points in connection with diurnal variations have been determined and discussed; and if ever the vexed problem of the cause of the daily variation in atmospheric pressure is completely solved, it will only be by the aid of this valuable series of papers.

In the Calcutta Memoir, which has only just reached us, the discussion embraces the temperature, pressure, and humidity observations, registered autographically

during the thirteen years 1881–1893, not merely with regard to the diurnal, but also the monthly and annual variations, together with a comparison of results at the other stations. This is probably one of the first complete discussions ever made of autographic records.

By adding on these thirteen years to the previous period of eye observations, a period is obtained sufficiently long to exhibit any secular periodicity, such as that in the mean sunspot period.

In the case of tropical air temperature, the existence of such a period is so well known that it has been frequently pointed out by Blanford, Eliot, and Hill in these Memoirs.

In the case of barometric pressure, as Mr. Blanford pointed out some years ago in his memorable discussion of the barometric see-saw between Siberia and Indo-Malaysia in the sunspot period, there is a small periodic variation of the barometric pressure of such a character that over India the pressure is above the normal in years about the minimum epoch of sunspots, and below it near those of maximum.

Calcutta, as Mr. Archibald states, is too near the axis of the see-saw (which is probably a little to the north of the Himalaya) to show a very marked variation; but the following figures for the mean cycle show that it has an existence, and must be reckoned with as a factor in the prevalent character of the weather in different years:—

Mean Annual Barometric Pressure anomaly at Calcutta (Alipore) in the eleven-year sunspot cycle from 1853 to 1893.

	Years of cycle.		Mean anomaly of annual barometric pressure unsmoothed. Inches.	
(1)	1853		−·0067	
(2)	1854		+·0007	
(3)		Two cycles intervene.	+·0132	Min. sunspot.
(4)			+·0077	
(5)			−·0012	
(6)			+·0042	
(7)			−·0032	
(8)	1893		−·0067	Max. sunspot.
(9)			−·0100	
(10)			−·0060	
(11)			−·0013	

These minute variations of pressure might appear too small to be associated with air movements and conditions of any considerable magnitude. It must, however, be remembered, especially by English meteorologists, that the barometric oscillation, corresponding to any given air-motion, is a direct function of the deflecting force of the earth's rotation, and therefore of the latitude. Consequently, a variation which would represent an insignificant disturbance in latitude 50° might be attended with serious consequences in India.

Thus the only marked feature of the great Madras drought and famine of 1876-77 was a slight excess of pressure over the whole area of drought, which nowhere exceeded ·04″ or ·05″ in amount.

The abnormal pressure conditions which enabled the Indian weather department to foretell accurately the last serious drought in India—that of 1891 in Rajputana—were small in amount, depending on variations and anomalies not exceeding ·05″, which is little more than one-third of the amount of the regular diurnal change between 10 a.m. and 4 p.m.

The range of pressure for the mean cycle for Calcutta in the present case is ·02″, and since the extreme range of annual means is only ·06″, it may be fairly presumed that the cyclical variation bears a sensible ratio to the variations which cause effective changes in the character of the years and seasons. When we further recollect the well-recognised fact that in Northern India the sunspot variations affect the summer and winter oppositely as regards rainfall, no doubts need be entertained that the state of the solar surface coincides with variations which are just as real, and probably no less practically important in their results, than those introduced by the diurnal and seasonal position of the sun in the sky.

It is indeed impossible to live in the tropics without being sensible of the reality of the sunspot influences. In years about the minimum spot epoch the mean annual temperature of the air is from one to two degrees higher, the range is increased, the wind force greater, and the rainfall less and more irregularly distributed than about the maximum epoch. Moreover, though the total sunspot effects are only a part of what occurs and are often masked by certain larger variations, whose origin is probably terrestrial and reactionary rather than solar and direct, the relation is recognised officially as a factor of practical importance, and allowed for in drawing up the forecasts of the summer and winter monsoons.

The whole subject of secular changes has received a decided impetus of late from the Memoir, Vol. vi. Part 2, on "Certain Oscillatory Changes of Pressure of Long and Short Period," by Mr. John Eliot, F.R.S. In this Memoir attention is drawn to a remarkable series of long-period waves of pressure over the Indian area, which vary from six months to two years in duration. The period investigated extends from 1875 to 1894.

These waves are believed to be of the nature of advances or checks in the general oscillatory system of air flow across the equator, which represents the so-called south-west and north-east monsoon winds of the Indian area.

As Mr. Eliot observes: "In part they are probably determined by seasonal conditions in Southern and Central Asia, and in part assist in determining the seasonal conditions in India, and perhaps also in Central Asia."

The extreme range of these fluctuations, measured by monthly abnormals over the whole period, amounts to about 0·118″, or about the same as the diurnal pressure range at sea-level in tropical India.

In discussing these waves, Mr. Eliot exhibits a similar series of oppositely phased oscillations in what are termed the vertical pressure anomalies between pairs of stations situated at considerable elevations in the Himalaya and on the adjacent plains.

These vertical anomalies (which are simply the variation at the hill stations *minus* the variation at the plain stations) are now so successfully employed in the preparation of the forecasts of the winter rains of Northern India, that they demand a little special reference.

In a country like India, where climatic changes far outweigh ephemeral weather changes, it is found that 95 per cent. of the irregular ephemeral changes of pressure are less in amount than the normal diurnal pressure range, the air movements are slow, massive, and regular in contrast with those of higher latitudes, and due quite as much to vertical as horizontal changes. It is therefore to be expected that the density or pressure of the lower mass of air between the hill stations at 7000 feet and sea-level, will often show variations of an entirely opposite character to that of the air above. In other words, abnormally high pressure below argues abnormally low pressure above, and *vice versâ*. As a matter of experience, this is found to be almost invariably the rule. When the pressure at the upper levels is lower than usual, the vertical anomalies would be *negative*, and when higher they would be *positive*. Mr. Eliot finds, moreover, that the vertical anomaly waves between stations such as Leh and Lahore, Murree and Peshawar, correspond all through to the long-period waves at the stations on the plains, but are exactly reversed in phase.

This shows either that the variation of flux is entirely confined to the lower atmosphere, or else that the vertical up and down flow remains temporarily uncom-

pensated at the higher levels. In any case, the conclusion is irresistible that the pressure variations are due to *flow* and not to a mere tidal rise and fall of the entire atmosphere.

A further proof that these so-called waves are connected with the seasonal transfers of air between Asia and the Indian Ocean, is the remarkable fact that the pressure variations at Mauritius are exactly contrary to those on the Indian plains, and *in general* similar to those of the vertical anomalies. In other words, the lower atmosphere over the Southern Indian Ocean and the higher Indian air strata are analogous termini of the harmonic oscillations in the general convective interflow over the monsoon and trade-wind area of Southern Asia and the Indian Ocean.

The chief critical epochs of both the vertical anomaly and general pressure anomaly curves observed over the plains, occur in March and November. These are, therefore, the months when the character of the ensuing season may be partially forecasted from an inspection of the pressure curves.

Experience has shown, as Mr. Eliot says, that "the primary maximum values of these oscillations [*i.e.* of the pressures on the plains] occur at the end of cold weather periods, characterised by abundant or excessive precipitation in Upper India and the Western Himalayas, and that the primary minimum values occur near or at the end of south-west monsoon periods during which the rainfall has been more abundant than usual."

If we remember that the cold weather rains occur in a stratum which mostly lies above the upper stations, and that the general variations above and below are almost invariably opposite in character, the empirical rule simply embodies the rational fact that the maximum rainfall occurs in connection with the minimum pressure of the containing air-stratum. Also since the vertical anomaly and plain pressure curves are inverse to each other, the rule may be put thus.

A descending vertical anomaly curve commencing about November, and a descending plain pressure anomaly curve commencing about March, indicate respectively the probability of heavy winter and summer rainfalls. Ascending curves commencing about the same epochs indicate the reverse seasonal conditions.

In the empirical form, these relations are now being successfully employed by the Indian Meteorological Department in its system of seasonal forecasts.

The marked tendency to a semi-annual or multiple semi-annual variation in the general pressure anomalies is curiously analogous to a similar period in cirrus bands noticed by Weber, in solar and lunar halos by Tromholdt, in the aurora Polaris, and in the spots and prominences on the sun.

What causes the equally marked differences which characterise the incidence of these barometric movements and their attendant conditions in different years, is still a mystery. Like most meteorological phenomena, they are probably a resultant of several components, solar, terrestrial, direct, and reactionary.

In any case, it is evident that the general outcome of these Indian meteorological researches, so far as relates to the question of long-period and universal weather changes, is decidedly encouraging, since it is plain that the majority of the anomalies in the Indian area are resoluble into harmonic periodic elements, leaving only a small residual to be labelled non-periodic and unpredictable. The moral, therefore, is not merely to extend terrestrial observation and the discussion of data over wide areas on broad, rational methods, but to endeavour to discover the precise way in which solar changes produce analogous long and short changes in terrestrial weather, especially where, as in India, these relations form such a dominant proportion of the total.

Since the above was written Mr. Eliot's interesting article on "Periodic Variations of Rainfall in India" has appeared.

Referring as it does particularly to the remarkable wave of rain and drought which has occurred during the past five years, it chiefly emphasises the remark made above, that the yearly anomalies in the general meteorological conditions are the resultant of several components—local, general, terrestrial, solar, direct, and reactionary. From the evidence adduced therein regarding the Indian Ocean area, and a general survey of conditions which have obtained in other parts of the world, it appears that this large oscillation has been of world-wide incidence. That it represents something in addition to the ordinary variations in the oscillatory flow of the trade-monsoon currents across the equator in the Indian Ocean. That it is therefore due to some abnormal extra-terrestrial—probably solar—influence, which must be referred to the solar physicists for its solution.

At the same time, its occurrence in no way invalidates the preceding conclusions deduced from a study of the ordinary yearly variations, or weakens the value of Mr. Eliot's vertical anomaly rule, as an empirical criterion of general monsoon characteristics.

MR. NEY ELIAS.

THE name of Mr. Ney Elias, whose death we briefly announced on June 17 (p. 159), is perhaps less familiar to the readers of travel and geography of to-day than it was to similar students of a quarter of a century since. In 1873 the Council of the Royal Geographical Society awarded him the Founders Medal for the successful accomplishment of a most remarkable journey through Western Mongolia. This was a district that no European had traversed since the days of Marco Polo, and notwithstanding the numerous difficulties which Mr. Elias overcame, and the personal danger in which he often stood, he was able to execute unaided a survey of the whole country travelled. The distance travelled was more than 2000 miles, starting from Kalgan, across the desert of Gobi, thence westerly to the Chinese frontier town Kwei-hua, and onward in a north-westerly direction to the Khangai range. The fanatical Mahommedan Mongol tribes, who were at war with the Chinese garrisons, prevented him journeying further to the south, to Kuldja, which was his proposed destination. The murderous devastation occasioned by this insurrection, and the impossibility of securing adequate assistance, compelled him to cross the Russian frontier and seek shelter at the town of Büsk. This journey, which he accomplished in about six months, was not his first experience in China. In 1871 he set out, with a single Chinese servant, to cross the entire continent of Asia, and a few years earlier had penetrated far into the interior with the view of discovering the causes that had forced the Lower Yellow River to forsake its bed and seek a new outlet to the sea. According to Chinese history, this river flowing through the great eastern plain of the country has had a very restless and eventful career. Nine times, within Chinese records, this river has varied its course, and sought a fresh estuary. The positions of the various mouths are scattered up and down the coast, covering, on the whole, five degrees of latitude. The date of the most recent of these fitful excursions is somewhat uncertain, but Mr. Elias concluded, from the observations which he made in 1867, that the change of bed was due to continuous flooding of the country in 1851-2-3, by which various barriers were broken down and changes of level produced. Mr. Elias was subsequently employed in India, and sent to Yunnan and Ladak; also undertaking a mission to Chinese Turkestan. Mr. Elias was a skilled observer in many branches of physics, and in the course of his travels enriched science by many observations. At

Bhamo, Sawuddy, and at Mandalay he carried on magnetic investigations and determined the variation. His longitudes are generally derived both by the method of lunar distances and by occultations. His skill as an observer is shown by the small differences that separate the results obtained by either method. At Mandalay, for example, the two values are separated by only a little more than a minute of arc. At Leh, actinometric observations engaged his attention; and if the series are not so long as those of Lieut. Hennessey and Mr. Cole, made at a station further south, they still possess great interest owing to the fact that the observations refer to a station so difficult of access. He rendered yeoman's service in the work of demarcating the frontier line between Burmah and the Shan States, and after a life of great adventure and of much service to science, he settled down as Consul-General at Meshed. For this most important post, and the management of the tangled web of diplomatic service, arising from its close connection with the Persian, the Russian, and the Afghan Governments, to say nothing of the restless Kirghiz tribes, he had admirably prepared himself. In 1885 he traversed the difficult Pamir country, and visited those districts on the banks of the Oxus, where may be met tribes of the most diverse races, and whose interests are as varied as the climates under which they dwell.

NOTES.

PROF. VIRCHOW, of Berlin, has been elected a Foreign Associate of the French Academy, in the place of the late M. Tchebicheff.

A CONFERENCE on the subject of the renewal of Antarctic exploration was held in the rooms of the Royal Geographical Society on Monday last, under the presidency of Sir Clements Markham. The main object of the conference was to induce the Australasian Premiers to bring the matter before their Governments, with a view to inducing them to contribute towards a British expedition under the auspices of the Royal Geographical Society. The conference was attended by, among others, the Duke of Argyll, the Marquis of Lothian, Sir Joseph Hooker, Admiral Sir George Nares, Admiral Sir Erasmus Ommanney, Admiral Sir W. J. L. Wharton, Sir John Kirk, Sir George Taubman Goldie, Prof. Rücker, and the Agents-General of Victoria, New Zealand and New South Wales. The Australasian Premiers were unable to be present. Speeches in favour of the object before the meeting were delivered by the chairman, the Duke of Argyll, Sir Joseph Hooker, Prof. Rücker, and the Agents-General. The chairman announced that the Council of the Royal Geographical Society were prepared to contribute any sum up to 5000*l.* to the amount which the colonial Governments might subscribe to the undertaking, and he expressed the hope that the matter might be pushed to a successful issue next year.

THE Institution of Naval Architects has, in honour of the Queen's Diamond Jubilee, organised an International Congress of Naval Architects and Marine Engineers, which was inaugurated by a conversazione on Monday evening. The congress itself was formally opened at the Imperial Institute on Tuesday by the Prince of Wales, who gave a short speech. On his departure, the chair was taken by the Earl of Hopetoun, the President of the Institution. After the President had delivered his address, papers were read by M. L. E. Bertin, on "Hardened Armour-plates and Broken Projectiles"; by Mr. C. E. Ellis, on "Non-inflammable Wood"; by Sir A. J. Durston and Mr. J. T. Milton, on "The History and Progress of Marine Engineering"; by M. P. Sigaudy, on "Water Tube Boilers." The session will conclude at Newcastle on July 15.

WE regret to announce the death, at the age of eighty-four, of Prof. J. J. Smith Steenstrup, of Copenhagen. After having acted as Lecturer on Mineralogy at Soröe, he was appointed, in 1845, Professor of Zoology and Director of the Zoological Museum at Copenhagen, retiring from his professorial activity in 1885. Prof. Steenstrup was the author of a number of scientific publications, several of which have been translated from the Danish into foreign languages.

AMONG other deaths we notice those of Dr. Alfred Stocquart, Chief Demonstrator of Anatomy in the University of Brussels, and Secretary of the Anatomo-Pathological Society, aged forty-one, of septic poisoning, contracted in making a post-mortem examination; and Dr. B. E. Cotting, for fifty-five years Curator of the Lowell Institute, Boston, Mass.

ACCORDING to a Reuter telegram of July 1 from Madrid, a dispatch from Manila gives some details of the eruption of the volcano Mayon. The village of Libong was completely destroyed, and 120 of the inhabitants were killed. The eruption was accompanied by a violent shock of earthquake.

THE Board of Regents of the University of the State of California have accepted the offer of Mr. C. F. Crocker, to defray all the expenses of an expedition to India to view the approaching eclipse of the sun. The expedition will remain in India from October next till June 1898.

INTENSE heat has prevailed for several days in Kansas and Arkansas, followed, on June 24, by destructive cyclones in Kansas and Missouri, and heavy storms in other States. During the storm at Hopkinsville, Kentucky, on the morning of the date mentioned, two earthquake shocks were felt. The vibrations were from west to east.

THE silver medal of the Zoological Society of London has been conferred by the Council on Mr. Alexander Whyte, who has lately retired from the post of Naturalist to the Administration of British Central Africa. Mr. Whyte accompanied Sir Harry Johnston when he first went out to Nyasaland in 1891, and has had the charge of the botanic garden at Zomba since that date, and performed other duties entrusted to him with zeal and fidelity. Under Sir Harry Johnston's instructions Mr. Whyte has made and sent to England from time to time large and most valuable collections in every branch of natural history. These have been transmitted to the British Museum through the Zoological Society of London, and have formed the subject of numerous communications by various experts to the scientific meetings of that Society. The fauna of Nyasaland, previously quite unknown, has thus become better understood than that of almost any other part of tropical Africa.

SIR MARTIN CONWAY and Mr. E. J. Garwood left London last week for Spitzbergen, their object being to continue the exploration of the interior of the main island begun by them last year. They are to be landed at King's Bay, whence they hope to make sledge expeditions over the northern ice sheet. They intend afterwards to revisit Horn Sound, and complete the scientific exploration of the southern peninsula.

DR. N. A. BUSCH, assistant-director of the Botanic Garden at Dorpat, has been commissioned by the Russian Geographical Society to undertake a botanical investigation of the Province of Kuban in the Caucasus, an almost unexplored territory. An assistant at the same Botanic Garden is also investigating the flora of the Government of Ssaratow.

A KEEPER in the service of the Zoological Society of London left London by the *Arundel Castle* on Saturday last, under arrangements sanctioned by the Colonial Office, to bring home

from Bechuanaland a young male giraffe, presented to the Queen on the occasion of her Diamond Jubilee by Chief Bethoen. The giraffe was captured three years ago, when quite young, in the Khalahari desert, and is now at Garanaka, ten miles north-east of Kanye, whither the keeper, on arrival at Cape Town, will proceed to receive it.

ANOTHER motor-cycle race is being organised in France. The date is fixed for August 22, and the course traversed will be from Paris to Cabourg, a distance of 215 kilometres.

A BIOLOGICAL station, containing aquaria, laboratories, rooms for collections and library, is in course of erection near Sebastopol, on the Black Sea. It is expected that the building will be opened for scientific work during the present year.

A LARGELY attended meeting, presided over by the Marquis of Tweeddale, was held on Friday afternoon last in the Botanical Theatre of University College, Gower Street, to inaugurate the personal memorial to the late Sir John Pender. The chairman handed over the sum of 5000*l.* to the College authorities to endow the electrical laboratory at University College, and announced that a portion of the amount subscribed had been expended on a bust of Sir John Pender, and that the balance would be given to the Glasgow University and the West of Scotland Technical College. Lord Kelvin, in a brief speech, said that it gave him great pleasure to have the opportunity of expressing his hearty concurrence with the resolutions of the Pender Memorial Committee as to the mode in which the fund collected should be distributed. He wished to speak of his own knowledge of what Sir John Pender had done. He remembered the first experiment that was made to lay a cable across the Atlantic. The scheme was supported by the then Mr. Pender, who in 1858 was one of the first directors of the company which was started to carry out the work. It was well within his recollection that all the directors resigned one after the other when the temporary success which attended the laying of the cable was followed so soon by failure. It was certainly a most discouraging result, but Mr. Pender was not to be disheartened. He was the only one to have the will and the power to keep the undertaking afloat, and from 1858 to 1864 he kept it afloat. The success which ultimately attended his efforts they all knew, and our colonies, he was glad to say, were now brought within speaking distance of the mother country.

A MONUMENT to the memory or Daguerre has been erected by public subscription at Bry-sur-Marne, and the inauguration ceremony was performed on Sunday, June 27. The memorial takes the form of a bronze bust placed on a stone pedestal, and is the work of Madame Bloch. At the close of the ceremony wreaths were placed upon Daguerre's grave.

THE outline programme of the Cardiff meeting of the Iron and Steel Institute, which is to take place from August 3 to 6, has now been issued. In it will be found full information as to each day's engagements. The following papers have been offered for reading: (1) "On Passive Iron," by J. S. de Benneville; (2) "On the Diffusion of Sulphides through Steel," by E. D. Campbell; (3) "On the Manufacture of Tin Plates," by George B. Hammond; (4) "On a Spectroscopic Analysis of Iron Ores," by Prof. W. N. Hartley, F.R.S., and Hugh Ramage; (5) "On Improvements in Shipping Appliances in the Bristol Channel," by Sir W. T. Lewis, Bart.; (6) "On the Iron Industry of Hungary," by D. A. Louis; (7) "On a Thermo-Chemical Study of the Refining of Iron," by Prof. Honoré Ponthière; (8) "On Carbon and Iron," by E. H. Saniter; (9) "On some Mechanical Appliances at Penarth Docks," by T. Hurry Riches; (10) "On the Application of Travelling Belts to the Shipment of Coal," by Thomas Wrightson.

THE *Times* Paris correspondent reports that at last Monday's sitting of the Academy of Sciences a paper by M. Tatin and Dr. Richet, on steam aerodromes, was read. The experiments of the authors are being carried on in emulation of those of Prof. Langley, the Secretary of the Smithsonian Institution, in Potomac Bay, near Washington. The French experiments have been made at Carquenez, near Toulon. The aerodrome weighed about 70 lb., or two and a half times as much as the American. The power of the engine was about the same—a little more than one-horse power. The French machine had two screws instead of one—one in front and the other behind. The maximum velocity obtained by MM. Tatin and Richet was greater, namely, 18 metres per second instead of 10, but the length of their run was 140 metres instead of more than a kilometre. The duration of the experiment was only a few seconds, instead of more than two minutes.

THAT science is being well fostered in our colonies can be gathered by a perusal of the *Transactions* of the Astronomical and Physical Society of Toronto, the seventh annual volume of which we have before us. This volume contains several interesting papers communicated by the active and corresponding members of the Society; and the numerous meetings seem always to have been well attended. The President's address delivered in January last, given in the volume, sums up the aim of the Society.

ATTENTION is called, in the *Engineer*, to a simple appliance intended as a substitute for the present crude method of fog-signalling on railways. The appliance is the invention of Mr. Pratt, of Bristol, and has recently undergone in a satisfactory manner a series of experimental tests on the West Lancashire Railway at Southport. The object of the invention is, in times of thick or foggy weather, when the ordinary danger signal would be invisible to the driver, to set automatically in operation the engine whistle, on passing the point where the ordinary fog detonator would be exploded. This is effected by a knife-cutter placed in the 6-foot way—and which is raised when the danger signal is put on—cutting through a brittle metal bar carried on the engine, the cutting through of which operates the lever acting upon the whistle, and which continues to sound until turned off by the driver, when the whole apparatus is automatically placed in position for operation when the engine again approaches a danger signal. The apparatus on the engine, which can be readily attached in any suitable position, consists simply of a pair of iron rods, between which slide, on half-rings, a series of the brittle metal bars referred to. When the bottom one is cut through it is thrown off, and brings down a lever rod attached to the engine whistle, which is at once set in operation; whilst the bar immediately above falls into its place, so that so long as the couple of rods between which these bars slide are kept supplied, the apparatus is always in readiness for signalling to the driver. The only real objection raised to the apparatus by the railway officials present was that it would be absolutely indispensable that every engine travelling over a line should be fitted with the appliance, and as over most main lines different railway companies have travelling powers, this would no doubt be a difficulty in the way of its adoption.

THE collection of Penguins in the Zoological Society's Gardens has received some valuable accessions in the shape of two examples of the little Blue Penguin of New Zealand (*Eudyptula minor*), and two specimens of the King Penguin from the Antarctic Seas, neither of which species are often seen alive in captivity. The former birds will be found in the Fish-house, where they are fed along with the other diving-birds, while the King Penguins have been located in an enclosure near

the Seal-pond, where they present a very attractive appearance with their sedate gesture and strangely contrasted colours. There are here also five examples of the Black-footed Penguin of the Cape to bear them company, but the King Penguins keep quite aloof from their smaller brethren.

IT is well known that the bison or buffalo (*Bison americanus*) is practically extinct in the United States as a wild animal, being now only to be found there in certain "parks" where it is carefully protected. But it is not generally so well known that there is still one district in the Dominion of Canada where the bison, or the variety of it called the "Wood-Bison," is still to be met with in its native wilds. The locality in question, which is perhaps one of the least accessible on the earth's surface, lies near Fort Chipewyan to the south of Great Slave Lake. It was visited in 1894 by Mr. Caspar Whitney, who has recently published an account of his unsuccessful hunt after this animal in his work entitled "On Snow-Shoes to the Barren Grounds." Before this interesting relict is quite exterminated, it is very desirable that a specimen of the Wood-Bison should be obtained for our Natural History Museum in South Kensington, where there is at present no specimen of this little-known mammal. It is probably only a local form of *Bison americanus*, but should certainly be represented in the National Collection.

A VERY compact and neat little camera has recently been put upon the market under the name of the "Photoscope," and is being made by Messrs. Ross and Co., of New Bond Street. This instrument is exactly like a binocular glass, and, in fact, it may be used as one when the fittings pertaining to the photographic attachment are removed. To use this for photographic purposes, one half of the binocular acts as a finder, and the other as the camera, the thicker ends of the binocular being placed up to the eyes, and pointed at the object to be photographed. The camera is arranged for carrying films, so that thirty or forty exposures may be made rapidly if required. The focussing is done after the manner of all binocular glasses, and the largest size picture capable of being taken by the instrument is 2 inches by 2 inches.

THE *Engineer*, commenting on a monograph by Mr. N. N. Banerjee, written under the auspices of the Bengal Government, says:—"The number of professional dyers in India is fast diminishing. Aniline dyes and cheap European goods are killing their trade. They are being compelled to turn their attention to new handicrafts, just as French competition and the vagaries of fashion caused the ribbon-makers of Coventry to seek a new livelihood in the manufacture of bicycles. Aniline dyes have made every man his own dyer. Formerly, the complicated processes by which indigenous dyes were prepared made the dyer a specialist. Now-a-days, anybody can dissolve the chemical powders sent out from Europe and colour his own clothes. The aniline dyes are more brilliant, and, to the native, they have the superlative merit of cheapness. They are not so fast, and they lack the delicacy of colour which, judging by the specimens annexed to the monograph, distinguish the Indian dyes. But their very gaudiness makes them more popular, and so the fate of the native dyer is sealed. Silk dyeing, cotton dyeing, and carpet dyeing are all declining. The fault, it should be added, is to some extent due to the conservatism of the native dyers themselves. They persistently adhere to their crude methods of preparing their dyes, and show a lamentable lack of ingenuity in preparing new designs."

THE *Weekly Weather Report* of June 26, shows that for the first half of this year the rainfall has exceeded the mean value in all districts, except in the north and west of Scotland. The greatest excess is in the south-west of England, where it amounts to 5 inches. This result is in some measure due to the occurrence of several heavy thunder-storms. During the week in question, some very high temperatures were recorded: Greenwich registered 90·2° in the shade, and 144·2° in the sun's rays, on the 24th, the day of the violent storm in Essex; while on the continent still greater heat was experienced, the shade temperature reaching 99° at Lisbon and Madrid, and 108° at Biskra (Algeria), in the early part of the week.

THE report of the Director of the Hongkong Observatory for the year 1896 states that the investigations of typhoons have been continued, and are now complete since the time of starting the Observatory in 1884. An important discussion of the anemometrical records obtained from the top of the Victoria Peak is being carried on, and will no doubt throw additional light upon the movements of the wind at elevated stations, which will be useful for storm-warning purposes. We notice that the weather forecasts during the year have been very successful, a result which is probably due to the receipt of three-hourly telegraphic reports, day and night, from Gap Rock Lighthouse, about thirty miles to the south of the colony. The examination of ships' logs has been continued with much activity; the observations for each month are tabulated in 10° squares, for the purpose of constructing trustworthy pilot charts of the Eastern seas. The number of observations so entered exceeds 131 thousand.

IN a note in NATURE for May 20, we called attention to Prof. Augusto Righi's investigations on electro-optics. Since then, we have received three further papers bearing on kindred theories from the same author. In one of these (*Atti dei Lincei*, vi. 10), Prof. Righi investigates the principal indices of refraction of selenite for electro-magnetic waves. In order to obtain a sufficiently large prism for his observations, the author had to make one of a number of small crystals cemented together with their axes parallel. In another paper, communicated to the Academy of Bologna (Bologna, Tipografia Gamberini, 1897), Prof. Righi deals with the orientation of a disc of selenite in a uniform electric field, and confirms Maxwell's theory according to which the three optical axes are coincident in direction with the three principal dielectric constants. A second communication to the Bologna Academy treats of secondary waves of dielectrics, and includes mathematical investigations for the effects of a dielectric sphere or cylinder.

WE have received a pamphlet entitled "An account of an investigation, by the late Joseph Baxendell, F.R.S., as to the short period cyclical changes in the magnetic condition of the earth, and in the distribution of temperature on its surface," by Joseph Baxendell, who read it recently before the Liverpool Astronomical Society. The author, from considerations arising out of an investigation of the irregularities which take place in the changes of some of the variable stars, was led to think that it was highly probable that the light of the sun, and also its magnetic and heating powers, might be subject to variations of a more complicated nature than had hitherto been supposed, and that changes indicated by the greater or less frequency of solar spots, others of a minor character and occurring in shorter periods, might also take place. A discussion of an immense amount of magnetical and thermometrical observations led the author to deduce the periods of variation, and conclude that (1) a ring of nebulous matter exists differing in density or constitution in different parts, or several masses of such matter forming a discontinuous ring, circulating round the sun in a plane nearly coincident with the plane of the ecliptic, and at a mean distance from the sun of about one-sixth of the radius of the earth's orbit. (2) The attractive force of the sun on the matter of this ring is alternately increased and diminished by the operation of the forces which produce the solar spots, being greatest at the times of minimum solar spot frequency, and least when the spots are most numerous. (3) The attractive force being variable, the

dimensions of the ring and its period of revolution round the sun will also vary, their maximum and minimum values occurring respectively at the times of maximum and minimum solar spot frequency. We may mention in this brief note that Leverrier was led to attribute a certain unexplained excess in the motion of Mercury's perihelion to the action of a disturbing body, a ring of small bodies, circulating round the sun within the orbit of this planet. It is stated in the paper that the eminent man of science, Dr. J. P. Joule, F.R.S., considered this hypothesis of Baxendell's very favourably, likening this supposed vibratory nebulous ring to a pendulum.

AN exhaustive memoir on the plague bacillus has appeared in the *Centralblatt für Bakteriologie*, and is from the pen of Dr. Rudolf Abel. In some respects this microbe resembles the cholera bacillus as regards its possible mode of distribution, and like it is apparently transmissible through water. Wilm states that he has discovered the plague bacillus in no less than three wells upon which suspicion had fallen. This investigator has also examined the vitality of the bacillus in various descriptions of water, and found it living for twenty days in distilled water. In well-water it survived sixteen days' immersion, and in sea-water six days. But these experiments were not quite satisfactory, inasmuch as considerable quantities of culture material were introduced into the waters along with the bacillus. Dr. Abel used distilled water and sterile, and also non-sterile, tap-water, and found that the plague bacilli in all cases were still living at the end of twenty days. In these investigations less culture material was added to the waters in question; but still it would have been undoubtedly better if the method had been adopted of first diluting the material of infection in water, so that the culture material was not *directly* introduced into the experimental waters. The plague bacillus is easily grown, and is very hardy, although in no instance have spore forms been discovered. Sunshine appears to be its most powerful natural enemy, for Dr. Abel found that one hour's insolation, when finely spread out in broth on cover-glasses, destroyed it. Kitasato in Hong Kong exposed bubonic pus on cover-glasses to sunshine, and found that the bacilli were killed in from three to four hours; similar results were obtained with pure cultures by Wilm. The bacillus is also sensitive to desiccation. Numerous investigations have been carried out by Dr. Abel on the action of disinfectants on the bacillus; and the memoir contains a mass of valuable information, gathered from various sources, on the character of this important micro-organism.

THE Secretary of Agriculture in the United States is arranging with recently-appointed ministers and consuls for an investigation of and report of agricultural conditions and work in the countries to which they are sent. Prof. Plumb, of Purdue University, Indiana, has been commissioned to report on the condition of dairying in certain countries he proposes to visit. Other specialists will go to Australasia and to Mexico, and the latter will collect specimens and data of what may be desirable from the semi-arid regions. Advantage will be taken of the visit of an expert to Central Asia, and tree seeds from there are expected. Prof. Hanson, of the Agricultural College of South Dakota, who is coming to Europe, will be sent on to Asia to bring back seeds of trees and legumes. Especial attention will be given to the search for vegetation of high and dry altitudes which may be introduced into America with success in similar altitudes.

THE June number of the *Mathematical Gazette*, published under the auspices of the Mathematical Association (formerly the Association for the Improvement of Geometrical Teaching), contains interesting papers on the projection of the sphere, by Prof. Alfred Lodge and by Mr. P. J. Heawood. Among the miscellaneous matter, teachers would do well to read Mr. R. F. Muirhead's brief note calling attention to certain flaws in the ordinary text-book treatment of uniform acceleration in dynamics.

AMONG the publications which have recently reached us attention may be directed to the *Photogram* for July, which contains several articles of interest. Dr. R. W. Shufeldt, in a short communication on the "Photography of Birds' Nests," pleads for good photographs of the nests of all birds that are nest-builders. His article is illustrated by a photograph of the nest of the cat-bird (*Galeoscoptes carolinensis*). Other articles in the same number are "Photography and Art," by C. E. Benham, and "The Restoration of Faded Prints," by A. Villain. In the latter two methods of restoration are described, and particulars given of a process by which greater permanence to photographic prints may be secured.—The *Irish Naturalist* has, as its leading contribution, "Some Observations by English Naturalists on the Fauna of Rathlin Island and Ballycastle District." The authors are R. Standen, Lionel E. Adams, G. W. Chester and J. Ray Hardy, who treat respectively of general observations, land and fresh-water mollusca of the Ballycastle District, the marine mollusca of Rathlin Island, and the Coleoptera of Rathlin Island.—The *Observatory* for July contains as frontispiece a striking photograph of the late Mr. E. J. Stone, F.R.S. In the July number of the *Strand Magazine* is the first of a series of articles by Grant Allen, entitled "Glimpses of Nature." The present instalment bears the attractive title of "The Cows that Ants Milk," and is well illustrated by F. Enock.—Another publication, the first part of which has just been issued, deserves mention. It is an album of pictures entitled "All about Animals," and contains well-executed reproductions of twenty of Gambier Bolton's well-known photographs.

THE additions to the Zoological Society's Gardens during the past week include a Campbell's Monkey (*Cercopithecus campbelli*, var.) from Appantoo, Coomassie, presented by Dr. Thomas Pigg; an Orang-outang (*Simia satyrus*) from Borneo, presented by Dr. H. Dohrn; a Bonnet Monkey (*Macacus sinicus*) from India, presented by Mr. James Callingham; a Common Squirrel (*Sciurus vulgaris*), British, presented by Lady Acland Hood; two Palm Squirrels (*Sciurus palmarum*) from India, presented by Mr. C. Ingram; a Vulpine Phalanger (*Trichosurus vulpecula*) from Australia, presented by Mr. M. A. Murray; a Common Seal (*Phoca vitulina*), British, presented by Mr. Wethenhogg; two Babirussas (*Babirussa alfurus*, ♂ ♀) from Celebes, presented by H.G. the Duke of Bedford; two White-crested Jay Thrushes (*Garrulax leucolophus*) from the Himalayas, presented by Mr. B. H. Jones; a Red-crested Cardinal (*Paroaria cucullata*) from South America, presented by Miss E. M. Kenyon Welch; a Blackbird (*Turdus merula*, var.), British, presented by Mr. A. Lawford Jones; eight Spotted Geckos (*Pachydactylus maculatus*), twenty-four Hispid Lizards (*Agama hispida*), thirteen Rough-scaled Lizards (*Zonurus cordylus*), two Delalande's Lizards (*Nucras delalandii*), two Three-streaked Skinks (*Mabina trivittatus*), two Aurora Snakes (*Lamprophis aurora*), two Infernal Snakes (*Boodon infernalis*), a Lineated Snake (*Boodon lineatus*), a Smooth-bellied Snake (*Homalosoma lutrix*), two Rough-keeled Snakes (*Dasypeltis scabra*), eleven Rufescent Snakes (*Leptodira kolambœia*), eight Crossed Snakes (*Psammophis crucifer*), five Rhomb-marked Snakes (*Trimerorhinus rhombeatus*), a Yellow Cobra (*Naia flava*) from Port Elizabeth, Cape Colony, presented by Mr. J. E. Matcham; a Salvadori's Cassowary (*Casuarius salvadori*) from New Guinea, two Gentoo Penguins (*Pygosceles tæniatus*) from the Falkland Islands, an Indian Dial Bird (*Copsychus saularis*) from India, a Banded Ichneumon (*Crossarchus fasciatus*) from Africa, deposited; a Tayra (*Galictis barbara*) from South America; two Black Cuckoos (*Eudynamis orientalis*), three Ruddy Finches (*Carpodacus erythrinus*) from India, purchased.

OUR ASTRONOMICAL COLUMN.

WEINEK'S LUNAR ENLARGEMENTS.—Selenographers will be glad to hear that Prof. Weinek proposes to publish a Lunar Photographic Atlas, which will contain an accurate and artistic representation of the whole visible surface of the moon. The materials that will form the basis and bulk of this atlas have been mainly derived from the series of negatives of the Lick Observatory, which have been enlarged twenty-four times. The maps will be printed by the phototype process direct from Prof. Weinek's enlarged glass diapositives, and will be constantly under his supervision and control during their reproduction by the Art Photographical Institute of Carl Bellmann in Prague. The proposed scale of the atlas will be 4 metres to the diameter of the moon; there will be in all 200 maps 26 × 31 cm., and each sheet will give the selenographical latitude and longitude for the centre of the picture, and also the selenographical longitude of the terminator for the latitude 0°. This will greatly facilitate the arrangement of the sheets according to the relative positions of the lunar objects they portray. The publication of such an atlas as this, which requires a great deal of outlay, cannot be undertaken unless a considerable number of subscribers are forthcoming. Prof. Weinek appeals in the first instance to all the observatories of the world to become subscribers for the ten issues, each to contain twenty lunar landscapes. There should be no difficulty in obtaining a sufficient number of applicants, as such a useful and epoch-making publication in selenography should be in the possession of every observatory.

MARTIAN MARKINGS.—In the current number of *Knowledge*, M. Antoniadi brings together in an interesting summary all the more important observations made from the year 1864 of that well-known marking on the surface of Mars, namely, Syrtis Major. The discussion shows that, on the whole, decided changes have taken place in the form of this marking, and that its expansion has invaded the regions occupied by Mœris Lacus and Lilaga. Two new canals have also been recorded during the last few years in this region. The diagramatic sketch, showing the gradual changes recorded during the last thirty-three years, brings out very clearly the reason of the disappearance of the lake as such mentioned above. M. Antoniadi remarks, as regards the displacements of "seas" and "lakes," that "absurd and imaginary as they might seem to the ordinary reader, they are simply familiar occurrences to the areographer. Evidently the surface of Mars has some fixed areographical markings; but the stability of the lesser details and of the polygonians of the canal system is so frail, that at times the changes assume a fantastic, grotesque, and almost ridiculous character."

LEAKAGE FROM ELECTRIFIED METAL PLATES AND POINTS PLACED ABOVE AND BELOW UNINSULATED FLAMES.[1]

§ 1. IN § 10 of our paper "On Electrical Properties of Fumes proceeding from Flames and Burning Charcoal," communicated to this Society on April 5, results of observations on the leakage between two parallel metal plates with an initial difference of electric potential of 6·2 volts between them, when the fumes from flames and burnings were allowed to pass between them and round them, were given. The first part (§§ 1–4) of the present short paper gives results of observations on the leakage between two copper plates 1 centimetre apart, when one of them is kept at a constant high positive or negative potential; and the other, after being metallically connected with the electrometer-sheath, is disconnected, and left to receive electricity through fumes between the two.

The method of observation (see Fig. 1) was as follows. Two copper plates were fixed in a block of paraffin at the top of a round funnel 86 centimetres long and 15·6 centimetres internal diameter. A spirit-lamp or a Bunsen burner, the only two flames used in these experiments, was placed at the bottom of the funnel, 96 centimetres below the two copper plates. One terminal of a voltaic battery was connected to one plate, and the other terminal was connected to the sheath of a Kelvin quadrant electrometer. The other copper plate was connected to one of the pair of quadrants of the electrometer in such a way that by pulling a silk cord with a hinged platinum wire at its end, this copper plate and this pair of quadrants could be insulated from the sheath of the electrometer and the rest of the apparatus. On doing so with no flame at the bottom of the funnel, no deflection from metallic zero was observed, even when the other plate was kept at the potential of 94 volts by the voltaic battery; this being the highest we have

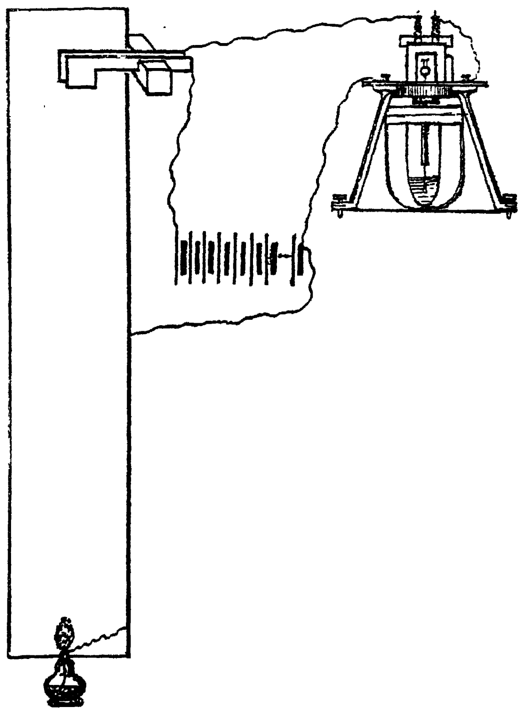


FIG. 1.

as yet tried. When the plate was kept at potentials of 2, 4 . . . 10 volts, the deflection from metallic zero in three minutes was observed; but for higher potentials, merely the times of attaining to 300 scale divisions from metallic zero were observed.

§ 2. The results obtained are summarised in the following table. In every case for potentials below 90 volts there was greater leakage when the uninsulated plate was connected to the negative terminal of the battery.

Spirit Flame.

Sensitiveness of electrometer = 60·7 scale divisions per volt. Hence 300 scale divisions corresponds approximately to 5 volts.

Difference of potential		+to plate, −to sheath		−to plate, +to sheath	
Volts		Deflection	Time	Deflection	Time
		Divisions	Min. Sec.	Divisions	Min. Sec.
2		+ 35	3 0	− 80	3 0
4		+ 92	3 0	− 133	3 0
8		+205	3 0	− 265	3 0
10		+240	3 0	− 311	1 15
Initial	Mean				
12	9·5	+300	0 53	− 300	0 38
18	15·5	+300	0 25	− 300	0 16
44·5	42·0	+300	0 4·5	− 300	0 4
89	86·5	+300	0 2·5	− 300	0 2·5

[1] Paper communicated to the Royal Society, Edinburgh, on July 5, by Lord Kelvin, G.C.V.O., F.R.S., and Magnus Maclean, D.Sc.

Bunsen Flame.

Sensitiveness of electrometer = 60·7 scale divisions per volt.

Difference of potential		+to plate, −to sheath		−to plate, +to sheath	
Volts		Deflection	Time	Deflection	Time
		Divisions	Min. Sec.	Divisions	Min. Sec.
2		+10	3 0	− 99	3 0
4		+73	3 0	−159	3 0
8		+200	3 0	−300	2 20
Initial	Mean				
12	9·5	+300	1 48	−300	0 48
16	13·5	+300	1 12	−300	0 30
19	16·5	+300	0 46	−300	0 18
31	28·5	+300	0 15	−300	0 13
47	44·5	+300	0 11	−300	0 8
75	72·5	+300	0 6·5	−300	0 5
94	91·5	+300	0 5	−300	0 4

§ 3. If the leakage in these experiments were proportional to the difference of potential, then the product of mean difference of potential into time should be constant for the same deflection from metallic zero. Taking the numbers obtained for the 300 scale divisions of deflection in virtue of the Bunsen flame, we have :—

Positive charge	Negative charge
s.	s.
9·5 × 108 = 1026	9·5 × 48 = 456
13·5 × 72 = 972	13·5 × 30 = 405
16·5 × 46 = 759	16·5 × 18 = 297
28·5 × 15 = 427	28·5 × 13 = 370
44·5 × 11 = 489	44·5 × 8 = 356
72·5 × 6·5 = 471	72·5 × 5 = 362
91·5 × 5 = 457	91·5 × 4 = 366

Thus it is proved that the leakage between two plates, each 10 square centimetres in area, 1 centimetre apart when the fumes from a Bunsen burner pass between them and round them, is approximately proportional to the difference of potential between them, when that difference is above 20 volts and up to 94 volts, the highest we have tried ; but that, below 20, it diminishes with diminishing voltages more than according to simple proportion.

§ 4. To determine the currents which we had in our arrangement, we took a movable plate of a small air condenser charged to a known potential, and applied it to the insulated terminal of the quadrant electrometer. In this way we found that a quantity equal to 0·15 electrostatic unit, gave a deflection of 300 scale divisions. Hence in the experiments with the Bunsen flame and with a potential of +94 volts kept on the uninsulated copper plate, the current to the insulated copper plate opposite to it, when 300 scale divisions was reached in 5 seconds, was—

$$\frac{0{\cdot}15}{3\times10^9}\times\frac{1}{5}=10^{-11}\text{ ampere.}$$

$$=\frac{1}{100000}\text{ mikro-ampere.}$$

§ 5. One of us about the year 1865, when occupied in experimenting with the latest form of portable electrometer, found that if it was held with the top of its insulated wire (which was about 33 centimetres long) a few inches below a gas-burner, a charge of electricity, whether positive or negative, given to this wire was very rapidly lost. The disinsulating power of flames and of hot fumes from flames was well known at that time, but it was surprising to find that cold air flowing up towards the flame did somehow acquire the property of carrying away electricity from a piece of electrified metal immersed in the cold air.[1] Circumstances prevented further observations on this very interesting result at that time, but the experiment was repeated with a portable electrometer in December of 1896, and we were made quite sure of the result by searching tests. During April and May of the present year observations were again made by means of (1) a multicellular electrometer reading up to 240 volts, and (2) a vertical electrostatic voltmeter (Fig. 3, p. 235) reading up to 12,000 volts. A steel wire 43 centimetres long was fixed to the insulated terminal of the multicellular electrometer, with its needle-point vertically below an ordinary gas-burner, as shown in Fig. 2.

§ 6. By means of a small carrier metal plate (a Coulomb's proof plane) a positive or negative charge was given to this wire and the quadrants of the multicellular till the reading on the scale was 240 volts. The leakage was then observed (*a*) with gas not lit, (*b*) with gas lit at different vertical distances above the point of the wire. We found that there was rapid leakage when the flame was one centimetre above the wire ; and the times of leakage from 240 volts to about 100 volts increased as the flame was raised to greater distances above the point ; or, otherwise, the

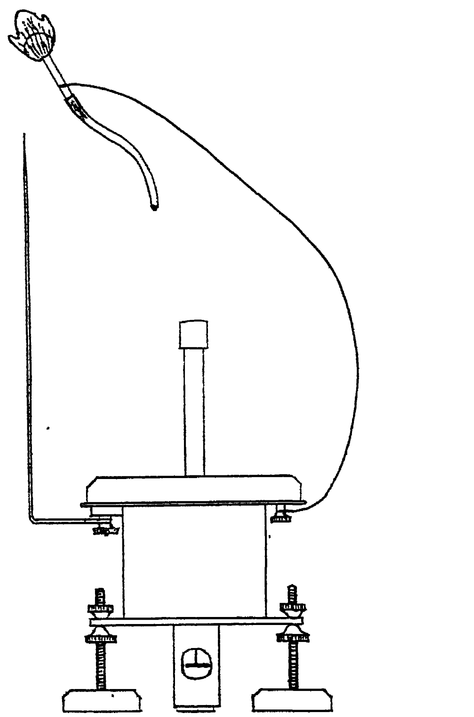

Fig. 2.

rate of fall of potential in one minute from 240 volts diminished as the distance of the flame above the point was increased. When the vertical distance of the flame above the point was 15 centimetres, or more, the time of leakage from 240 volts was practically the same as if the flame was not lit at all. A plate of metal, glass, paraffin, or mica, put between the point and the flame, diminished the rate of leakage. The leakage from 200 volts during the first minute is given in the following table, for different distances of the flame, with no intervening plate.

Distance of flame above point	Leakage during one minute	Remarks
Centimetre	Volts	
1·0	200 to 60 = 140	
1·5	200 to 92 = 108	
3·0	200 to 179 = 21	
6·0	200 to 196 = 4	
	200 to 197 = 3	No gas lit, but wire on the electrometer as in the other tests.*

* We sometimes found the multicellular electrometer to insulate so well that in five minutes there was no readable leakage from 240 volts.

[1] We have recently (June 1897) found the following statement, in Worthington's communication to the British Association (1889 Report, pp. 225, 227) "On the Discharge of Electrification by Flames" ; . . . "the observation seems to have been made by Priestley, that the discharge takes place *with apparently equal rapidity*, if the rod be held at the side of, or even below, the flame at the distance of, say, five centimetres" The four words which we have italicised are clearly erroneous, as we find *enormously greater leakage* five centimetres above a flame than five centimetres below it : but it is very interesting to learn that Priestley had found any leakage at all through air five centimetres below a flame.

§ 7. Similar experiments were made with higher voltages measured by the vertical electrostatic voltmeter, and we found that when the flame was three or four centimetres above the point, there was very rapid discharge; but when the flame was 60 centimetres or more above the point, the leakage from 3500 volts was practically the same as if the flame was not lit.

In place of the metal point, a round disc of zinc, 8 centimetres in diameter, was fixed, as shown in Fig. 3, to the end of another steel wire of the same length; and leakage from it to the flame above it, observed. For the same distance between the flame and either the point or the metal disc, the rate of leakage through the same difference of potential, was *less for the point than for the disc*. Thus with the flame 25 centimetres above the point the time of drop from 3000 volts to 2000 volts was 1 min. 53 secs., and with the flame the same distance above the horizontal plane of the disc the time of drop from 3000 volts to 2000 volts was 1 min. 14 secs. *This is a very important result.*

§ 8. Experiments were next made to find if, and if so, how much, the leakage is diminished by putting non-conducting plates of glass, paraffin, mica, between the point or disc and the flame. At a corner of each plate was pasted a little square of tinfoil, so

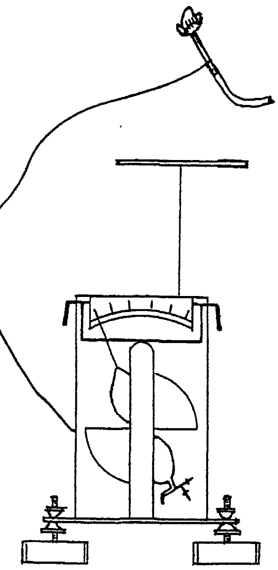

FIG. 3.

as to prevent any electrification of the non-conducting substance by handling. These pieces of tinfoil were always kept metallically connected with the sheath of the electrometer. Each plate was fixed with its under surface 1 cm. above the steel point. In preliminary experiments (of which a continuation is deferred until the insulation of the electrometer is made practically perfect by coating its vulcanite insulators with paraffin) the following numbers were obtained:—

I. *Glass Plate* 18 *cms. by* 19 *cms. by* 0·3 *cm.*

Distance of flame above point	Time of fall from 3000 to 2000 volts		Remarks
Cms.	Min.	Sec.	
—	5	30	Insulation test, with no flame.
12	2	5	Flame lit: no intervening plate.
,,	4	7	,, ,, glass plate between.

II. *Mica Sheet* 18 *cms. by* 9 *cms. by* 0·1 *cm.*

—	6	46	Insulation test, with no flame.
12	1	56	Flame lit: no intervening plate.
,,	3	50	,, ,, mica sheet between.

III. *Paraffin Plate* 11 *cms. by* 11 *cms. and* 0·75 *cm. thick.*

—	6	40	No flame. Insulation test.
12	1	53	Flame lit: no intervening plate.
,,	2	20	,, ,, paraffin plate between.

We hope to return to the investigation with the insulation of the electrometer perfected; and to determine by special experiment, how much of the fall of potential in the electrometer in each case is due to the electricity of opposite kind induced on the uppermost surface of the non-conducting plate, and how much, if any, is due to leakage through the air to the metal disc or point below.

§ 9. To test the quality of the electrification of both sides of the non-conducting plates of glass and paraffin, a thin copper sheet was fixed to one of the terminals of a quadrant electrometer, as represented in Fig. 4, where A is the plan of plate C attached to the electrometer, and B is the plate of paraffin or glass under test.

In the primary experiment (Fig. 3) the non-conducting plate was fixed in a horizontal position one centimetre above the electrified metal (point or disc), and eleven centimetres below the flame. A charge was given to the metal, to raise its potential to about 3500 volts. After some minutes, generally till the potential of the metal fell to 2000 volts, the non-con-

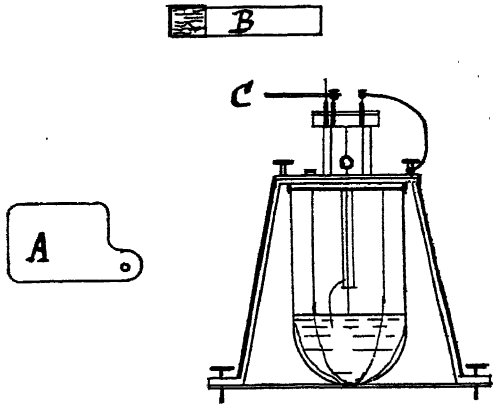

FIG. 4.

ducting plate was removed and placed, as shown in Fig. 4, above the metal plate C attached to the quadrant electrometer, and the deflection was observed. For a thin piece of glass (0·3 cm. thick) the whole effect of the two sides was negative when the electrified metal point or disc had been charged positively and *vice versâ*. But on putting two plates of glass above the electrified metal, we found the top plate to be oppositely charged and the under plate to be charged similarly to the point or disc, but not so highly. We found corresponding results with a plate of paraffin 0·75 cm. thick, and with two plates of paraffin 0·5 cm. and 0·75 cm. thick. When a plate of paraffin 3·25 cms. thick was used, we always found the top face charged oppositely to the charge of the metal, whether disc or needle-point, and the under face charged similarly to the metal below. Thus the apparent total charge of the two faces of a thin non-conducting plate is due to the fact that the face of the plate away from the electrified metal is more highly charged oppositely than the face next the metal is charged similarly.

A NEW LAW OF HEREDITY.

THE truth of a law of heredity proposed by Mr. Francis Galton, has been verified in particular instances, in a memoir[1] read by him before the Royal Society on June 3.

He first put forward the law, with hesitation, in his book "Natural Inheritance" (Macmillan and Co., 1889), page 134, because it was founded at that time almost wholly upon *à priori* grounds. Now, being found to hold good in a large group of

[1] "The average Contribution of each several Ancestor to the total Heritage of the Offspring," by Francis Galton, D.C.L., Sc.D., F.R.S.

cases, there is strong reason for its acceptance, as applicable generally to all qualities in all the higher (bisexual) animals. When it is applied to individual cases, minor corrections should of course be made in respect to sexual limitations, prepotencies of particular ancestors, and the like.

The law shows the proportion of the heritage that is contributed on the average by each parent, grandparent, great-grandparent, and so on. There *must* be an *average* contribution, drawn from each ancestral place *independently* of all the rest, because cases are familiar to observers in which a peculiarity found in some single ancestor has appeared in one or more of the offspring; the present law expresses its amount.

The general considerations upon which the law was originally founded, are four in number but not equally cogent; there is only one solution that satisfies them all. (1) The consequence of limitation in space on *particulate* germinal matter, which necessitates the loss of one-half of the total germinal material contributed by the two parents. This is confirmed by the commonly (though not universally) accepted fact of observation in the life-history of the germ. (2) The remark already made, that any ancestor however remote *may* contribute his peculiarity independently of the rest. (3) The contribution of the two parents to the child, being analogous to that of the 4 grandparents to the 2 parents, of the 8 great-grandparents to the 4 grandparents, and so on, make it probable that the latent links of the chain of ancestral contributions form a geometric series of terms, diminishing as we proceed from the ancestor downwards. (4) The sum of the contributed heritages must be equal to 1.

These four conditions are satisfied by the series $\frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \frac{1}{16} +$&c. In other words by the supposition that the two parents contribute between them $\frac{1}{2}$ of the total heritage of the child; the four grandparents, $\frac{1}{4}$; the eight great-grandparents, $\frac{1}{8}$, &c. Or again, that a single parent contributes $\frac{1}{4}$; a single grandparent, $\frac{1}{16}$; and a single ancestor in the nth generation, $1/2^{2n}$. A noteworthy consequence of this is that all the 16 great-great-grandparents taken together, are no more efficient than a single grandparent, and only one quarter as efficient as a single parent.

This supposition does not run counter to the commonly accepted view that the true line of descent stretches from germ to germ, and not (except in, perhaps, a small degree) from person to person; the person must on the average be a fair average representative of the germ, consequently statistical averages which are true of the one, would be true of the other, also.

The verification of the above theory is the object of Mr. Galton's memoir. Appropriate materials for the purpose were at last found in the registered colours of the pedigree stock of Basset hounds. This stock was started some twenty years ago by Sir Everett Millais, who purchased on the continent 93 selected hounds for the purpose, and has subsequently interbred their most valuable descendants. A Basset Club has long been established, which publishes an occasional stud-book (the latest was in 1896) containing the registered name, parentage, date of birth, and breeder of each hound. The colours are not printed in it, but they are always entered on the form sent by the breeders to the Club, and Sir E. Millais kindly had them copied for his use. Now there are two, and only two, recognised varieties of these colours: the one technically known as *lemon and white* (the word "lemon" standing for any shade between yellow and reddish-brown), and the other known as *tricolour*, from its containing black as well. So there are only two alternative conditions to be considered: "with black" and "without black"; or "Tricolour," and "Non-tricolour"—say for brevity, T. or N. It is asserted that intermediate and doubtful cases between T. and N. hardly exist.

The result is a collection (1) of 817 hounds of registered colours, T. or N., descended from parents whose colours are also known. (2) Of these, in 567 cases, the colours of all four grandparents are known; again (3) of these, in 188 cases, the colours of all eight great-grandparents are known. These three sets form the material that is tabulated and discussed, and supplies the requisite means for comparing calculated results with observed ones.

There are numerous points dealt with in the memoir, and explained away, to which there is not space to speak of here; one only need be mentioned, namely the question whether either the sire or the dam is so prepotent in transmitting colour, as to make it necessary to treat the sexes apart. It proves that the dam is prepotent over the sire in this respect, but only in the proportion of 6 to 5; also that the neglect of sex made no sensible difference in a test case. Consequently all ancestral places in the same generation are treated as of equal average efficiency. In short, if n be the order of any given generation (counting $n = 1$ for parents, $= 2$ for grandparents, &c.), there are 2^n ancestral places in the nth order, and these contribute between them $1/2^n$ of the total heritage; consequently each ancestral place contributes $1/2^{2n}$ of it. If the same hound fills more than one ancestral place, he has to be rated separately for each of them.

The contributions from the unknown ancestry are reckoned as follows. It was found that 79 per cent. of the parents of T. hounds are T. also, and that 56 per cent of the parents of N. hounds are T.; consequently the unknown grandparents, great-grandparents, &c., of the T. hounds would have probably $(\cdot79)^2$, $(\cdot79)^3$, &c., of T., and those of the N. hounds would have $(\cdot56)^2$, $(\cdot56)^3$, &c., of T. A simple calculation shows that the sum of the T. contributions to the offspring of the unknown ancestry of each T. grandparent would be 0·0408, and that of each N. grandparent would be 0·0243; these values are used in discussing the set (2). In set (3) the great-grandparents are known, ignorance beginning above that stage; in this case, the pre-ancestral contribution of T. through each T. great-grandparent, is found to be 0·0102, and that through each N. great-grandparent is 0·0061. There is no need here to allude to minor corrections, noticed in the memoir, whose effect is too small to be worth regarding.

It thus becomes a very simple matter to determine the contribution from each several known ancestor as well as that from the unknown ancestry of each of them, and, by adding these together, to obtain a coefficient appropriate to any given group of similar cases, such as when multiplied into the total number of offspring, shall give the "calculated" number that are T.

The test of the truth of the theory lies in the accordance between these calculated numbers and the observed number.

Owing to the large proportion of T. hounds and to selective breeding in favour of T., the different possible matings are by no means equally common, those in which the known ancestry are all (or nearly all) N. being non-existent. The results for such as occurred, are summarised below (excluding seven cases, falling into three groups, that lay outside the limits of the Table for set 3). The coefficients are added to show the degree of variety in the test conditions. Fuller information is to be found in the Tables published in the memoir, out of which these figures are extracted.

CALCULATED AND OBSERVED VALUES COMPARED.

Set 2.

Coefficient...	·91	·83	·76	·68	·66	·58	·51	·43	·26	·18	—	Total
T. calculated	108	99	21	8	24	92	30	3	5	1	—	391
T. observed	106	101	24	8	20	79	36	4	7	2	—	387

Set 3.

Coefficient...	·96	·94	·92	·90	·87	·85	·83	·81	·81	·79	·77	
T. calculated	2	24	13	14	16	18	13	5	2	3	2	(continued)
T. observed	2	25	14	15	17	19	14	6	2	2	3	

Set 3 (continued).

Coefficient...	·75	·69	·67	·65	·64	·62	·60	·58	·56	·54	·52	Total
T. calculated	2	1	1	6	1	17	8	18	5	2	7	180
T. observed	2	1	0	5	1	16	12	8	9	1	7	181

Comparing the totals of each of the two sets, we see that the calculated results are practically identical with the observed ones, 391 with 387; 180 with 181; grand total, 571 with 568. There is therefore no *constant* error, the errors in individual

cases balancing one another. When we examine the several groups, 32 in number, which contribute towards the above totals, a remarkable amount of agreement is shown throughout between calculation and observation, such as would raise the art of breeding to a science of considerable precision. The most notable exception is in the sixth column of set 2, where the numbers are 92 and 79, but, as is shown in the memoir, the observed values run there so irregularly with their neighbours, that they cannot be accepted as true representatives. The causes of heterogeneity undoubtedly include the disturbing effects of close interbreeding, because particular hounds of good shape that have also considerable prepotency, are largely bred from.

The author mentions that he had made experiments with the coefficients, altering them slightly and recalculating, and that he found in every case a notable diminution in the accordance between calculation and observation; the test that the law has successfully undergone thus appears to be even more severe and searching than might have been anticipated.

It is hardly necessary to insist on the value to breeders of a trustworthy law of heredity. Vast sums are spent annually in rearing pedigree stock of the most varied kinds, such as horses, cattle, sheep, pigs, dogs, and other animals, besides flowers and fruits. Certainly no popular view at all resembles that which is put forward and justified in Mr. Galton's memoir, which is epitomised here so far as space admits.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Maine State College at Orono will in future be known as the University of Maine.

MR. MUIR, of Halifax University, has been appointed to the chair of Psychology in Mount Holyoke College.

THE Victoria University on Saturday last conferred on Sir George Gabriel Stokes, Bart., the honorary degree of D.Sc.

THE Rev. D. J. Thomas has been appointed Principal of the Home and Colonial Training College, Gray's Inn Road, and of the Highbury Training College for Secondary Teachers.

THE establishment of a fresh-water biological station at Hemlock Lake, under the direction of Prof. Charles W. Dodge, has been sanctioned by the Board of Trustees of the University of Rochester, U.S.A.

THE library building of the University of Iowa was on June 19 struck by lightning, and destroyed by fire. The physical laboratory was on the first floor of the building. The total loss is estimated at about £20,000.

AMONG recent appointments may be mentioned:—Dr. Brault, to be Professor of Tropical Diseases at Algiers; Prof. W. Th. Engelmann, of Utrecht, to be Professor of Physiology at Berlin, in place of the late Prof. du Bois-Reymond.

THE following resignations are announced:—Dr. James Woodrow from the presidency of South Carolina College; President Craighead and Profs. Tompkins and Wright from Clemson College; Dr. W. H. Hervey from the presidency of the Teachers' College, New York.

ACCORDING to *Science*, Prof. Edward L. Nichols, the President of the New York State Science Teachers' Association, has appointed a committee of nine to consider and report at the next annual meeting of the Association on the following topics:—"Science as an Entrance Requirement to Colleges," "Science Teaching in the Secondary Schools," "Nature Study in Primary Schools."

THE June issue of the *London Technical Education Gazette* contains particulars of various courses of science lectures which are to be given in the autumn and winter of this year at University and King's Colleges, and at the Battersea and South-West London Polytechnics. Many of the courses are quite free of charge, and as only a limited number of persons can be accommodated at some of them, early application is desirable.

UNDER the auspices of the American Society for the Extension of University Teaching, a summer meeting is being held at the University of Pennsylvania from July 6 to 30. *Science* announces that two lectures on "Mediæval Science" will be given by Prof. W. F. Magie, and lectures on "Forestry" and "Museums" will be delivered by Prof. J. T. Rothrock and Prof. W. P. Wilson respectively. In Psychology courses of lectures are announced by Prof. L. Witmer, Prof. J. M. Baldwin and Prof. E. B. Titchener. Conferences on the teaching of geography will be led by Profs. W. M. Davis and R. E. Dodge.

SCIENTIFIC SERIALS.

Symons's Monthly Meteorological Magazine, June.—Hailstorm at Seaford, Sussex, May 30, 1897. It can be very rarely proved that a shower of hailstones as large as a hen's egg has fallen over a considerable area in England, but from letters received from various observers this is shown to have been the case during thunderstorms which occurred over the east of England on that day between the Isle of Wight and Lincoln. At Seaford several hailstones were picked up measuring 4½ inches round, and at Maidstone the stones were as large as walnuts; the noise there was so great that the services in nearly all the churches were interrupted.—Heavy rain at Port Elizabeth, Cape Colony, May 5, 1897. The amount measured between 8 a.m. and 1.30 p.m. was over 5 inches, and in three days 7·29 inches were measured.

Bulletin de la Société des Naturalistes de Moscou, 1896, No. 2.—New tertiary mammals found in Russia, by Mme. Marie Pavloff, with one plate (in French). The most important find is that of a bone which was identified as the lower end of the third metacarpus of *Anchitherium aurelianense*, Cuvier; thus being the first *Anchitherium* rest found in Russia. It comes from the neighbourhood of Nikolaieff, where it was found in a layer containing remains of *Mastodon borsoni*. The other remains belong to the Pliocene yellow "Balta Sands," and are: *Rhinoceros Schleiermacheri* (Kaup), *Capreolus cusanus* (Crois. and Job., *teste* Boyd Dawkins), and *Mastodon turicensis* (Schintz). They throw a new light on that interesting formation.—The reptiles of Europe, by Dr. J. Bedriaga, Part ii. *Urodela*. A most elaborate work (in German), containing full indexes of literature, synoptic tables for determination, and full detailed descriptions of the species (to be continued).—On the structure, &c., of the Nematocysts of Cœlenterata, by N. Iwanzoff, with two plates (in German, concluded).—Polar Land and Tropical Flora, by H. Trautschold (in German). Deichmüller having shown that the invariability of the rotation-period of the earth is not probable, and a variation in the position of the earth-axis having been proved, Prof. Trautschold enumerates the geological data, which render very probable that the position of the axis has been slowly displaced in geological times, and which could not be explained otherwise.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 13.—"Further Note on the Influence of a Magnetic Field on Radiation Frequency." By Prof. Oliver Lodge, F.R.S., assisted by Mr. Benjamin Davies.

Referring to a former communication of mine, on the subject of Zeeman's discovery, printed on page 513 of the *Proceedings* of the Royal Society for February 11 this year, vol. lx. No. 367, I wish to add an observation to those previously recorded, as I have recently acquired a concave Rowland grating ($3\frac{1}{2} \times 1\frac{1}{2}$-inch ruled surface, 14,438 lines to inch, being the one used by Mr. George Higgs), of which the spectra of the first and third orders on one side are very satisfactory.

It is said on page 513, "If the focussing is sharp enough to show a narrow, dark reversal line down the middle of each sodium line, that dark line completely disappears when the magnet is excited." With the greater optical power now available the dark reversal line is often by no means narrow, and though in some positions of the flame it does still tend to disappear or become less manifest when the flame is subjected to a concentrated magnetic field, the reason of its partial disappearance is that it is partially reversed again—*i.e.* that a third bright line, as it were, makes its appearance in the midst of the dark line, giving a triple appearance to each sodium line.

The following is a summary of the different appearances that may be seen according to the state of the flame and the strength of the field:—

At low temperature, and with the flame forward in the field, when each sodium line is sharp and single, magnetism widens it,

and with a little more power doubles it, causing a distinct dark line down its middle. The same effect occurs with lithium and thallium lines.

At higher temperature, and with the flame partially behind the field, when each sodium line appears as a broad hazy-edged double, magnetisation greatly widens the doubling, pushing asunder the bright components very markedly; stronger magnetisation reverses the middle of the widened dark band, giving a triple appearance; stronger magnetisation still reverses the middle once more, giving a quadruple appearance to the line. In every case a nicol, suitably placed, cuts off all the magnetic effect and restores the original appearance of the line.

The same thing is seen when salts of lithium or of thallium are introduced into the flame; and the components of the doubled red lines are more widely separated than the components of the doubled green lines, the effect being proportional to wave-length. The most interesting line to try was the red cadmium line, since this has been proved to be of specially simple constitution by Michelson. We have recently been able to get the cadmium spectrum well developed by means of a sort of spark arc between the magnet poles, maintained by an induction coil excited by an alternating machine, and we find that the magnetic doubling of the chief lines occurs in precisely the same way with the spark spectrum as with the flame spectrum, and that the red cadmium line behaves in the same way as the others. The magnetic effect is better seen from a direction perpendicular to the line of force when a nicol is interposed in the path of the light, but rotation of the nicol, through 90°, cuts it entirely off, accurately so where a small spark is the source of light.

June 17.—"Kathode Rays and some Analogous Rays." By Silvanus P. Thompson, F.R.S.

(1) The size of the kathodic shadow of an object depends upon its own electric state, as already found by Crookes (*Phil. Trans.*, 1879, Part ii. p. 648). If it is negatively electrified the shadow expands. If it is positively electrified the shadow contracts. The position, as well as the size of a kathodic shadow, may be affected electrostatically; the rays which cast the shadow being repelled from a neighbouring body if the latter is negatively electrified. In some cases the contraction of the shadow of a narrow object that is made positively electrical (anodic) may go so far that the luminous margins approach and even overlap, giving the appearance of a bright or negative shadow in place of a dark one. The enlargement of a shadow when the object is made kathodic, and the diminution of the shadow when the object is made anodic, both depend upon the degree of exhaustion of the tube; and both are augmented up to a certain point by raising the degree of exhaustion. The enlargement when the object is made kathodic vastly surpasses the diminution when the object is made anodic. Kathode rays are capable of being deflected electrostatically; being apparently strongly repelled from a neighbouring kathodic surface, and less strongly attracted towards a neighbouring anode. Two kathode beams from two small disc kathodes can cross through or penetrate one another without interfering with another.

(2) Objects protected by a non-conducting layer of glass do not at moderately low exhaustions, when made kathodic, repel or deflect kathode rays, and their shadow does not enlarge. But at a certain minimum exhaustion they suddenly exert an electrostatic deflection. Naked objects made kathodic deflect the kathode rays at all exhaustions.

(3) Kathode rays cannot be concentrated by reflection either from a non-conducting or a conducting surface, nor by passage through a metal tube which is itself negatively electrified.

(4) When kathode rays strike upon an internal metal target or anti-kathode there are emitted from the latter (both at exhaustions lower than suffice to produce Röntgen rays, and at exhaustions at which those rays are also produced) some internal rays resembling ordinary kathode rays in the following respects:—They produce a similar luminescence of the glass; they cast shadows of objects; they are susceptible of deflection both magnetically and electrostatically. But they produce no Röntgen rays where they fall upon the glass surface. They do not follow either the law of specular reflection, nor that of diffuse reflection, but are emitted from the anti-kathode surface apparently according to a similarly anomalous distribution to Röntgen rays, *i.e.* with nearly equal intensity, at all angles up to 90° with the normal. It is proposed to call these rays *para-kathodic* rays in contradistinction to the ordinary or *ortho-kathodic* rays. From the similarity of their distribution with that of the Röntgen rays it is inferred that the physical processes concerned in their production are identical. These para-kathodic rays are emitted from the anti-kathode both when the latter is made an anode, and when it is neutral or even made kathodic. From an anti-kathode there may proceed at one and the same time, and in one and the same direction para-kathodic rays and Röntgen rays, which, meeting an interposed object, may cast simultaneously two shadows—a para-kathodic shadow on the glass, and a Röntgen shadow on an external screen of barium platinocyanide. The former shadow can be deflected by a magnet, the latter cannot. The former shadow expands if the object is made kathodic; the latter does not.

(5) If thin metal screens are used to sift the kathode rays the luminescent phenomena change. The rays of least penetrating power appear to be most susceptible to magnetic and electrostatic forces. The various constituents of a heterogeneous kathode beam are emitted in various proportions at different degrees of exhaustion. In the kathode rays emitted at higher degrees of exhaustion there is a greater proportion of the less-deflectable rays. The least-deflectable rays are those which most readily penetrate through a perforated screen when that screen is itself negatively electrified.

When ordinary kathode rays fall upon a perforated screen which is itself made kathodic, or are attempted to be passed through a negatively electrified tube, there emerge beyond the screen or tube some rays, here termed *dia-kathodic* rays, which differ from the ortho-kathodic, and also from the para-kathodic rays. These dia-kathodic rays are not themselves directly deflected by a magnet. They show themselves as a pale blue cone or streak. Where they fall on the glass they do not excite the ordinary fluorescence of the glass. The dia-kathodic rays excite, however, a different or second kind of fluorescence; the tint in the case of soda-glass being a dark orange. Intervening objects in the beam or cone of dia-kathodic rays cast shadows. The orange fluorescence evoked on soda-glass by the dia-kathodic rays shows in the spectroscope the D lines of sodium only. The shadows cast by dia-kathodic rays are not deflected by the magnet, nor do they change their size when the object is electrified.

"Fifth Report to the Royal Society Water Research Committee." By H. Marshall Ward, F.R.S., Professor of Botany in the University of Cambridge. Presented to the President and Council, December 10, 1896.

The following conclusions show the principal points resulting from three years' study of the Bacterial Flora of the Thames:—

(1) Very many forms occur in the Thames, some of which are pathogenic under certain conditions.

(2) The "species" of the descriptive hand-books—principally medical—are frequently not species at all, in the botanical sense, but varieties, or growth-forms, the distinctive characters of which are not constant. These so-called species need revision and grouping around types, which may turn out to be the true species.

(3) The characters derived from the behaviour of colonies are not sufficient for the determination of species, and how far they may be employed in conjunction with other characters will only be elucidated by advances in our knowledge of the way the colonies are built up by the growing bacteria on the given media.

(4) The effects of definite changes in the environment on the media are of great importance, but have hardly been noticed as yet. Plate-colonies on gelatine, for instance, develop quite differently, according to the condition of the gelatine; so that a feeble and slow-growing bacterium produces colonies quite unlike those developed by the same species when vigorous and quickly growing, not only owing to its peculiarities of growth as a feeble form, but also because the gelatine has altered during the intervening period.

(5) The effect of changes of the environment on the growing organism itself is recognised as important.

(6) With especial reference to the Thames bacteria, the past history of the organism isolated from the river implies causes of variation. The river water is a poor nutritive medium, and the organism is exposed to great changes of temperature, light, movement, &c., during its sojourn therein. Consequently the time it has been in the river affects the behaviour of the organism when isolated, just as we know that a bacterium is affected by the previous conditions of its culture in other media. Hence two colonies on a plate may look very different, and yet belong to the same species, one being developed from a cell

that had been many days or weeks in the water, the other from one that had only been there a few hours. It may need weeks or months of cultivation under constant conditions to establish the identity of the two.

Linnean Society, May 24.—Anniversary Meeting, Dr. A. Günther, F.R.S., President, in the chair.—The report of the Librarian having been read, the President opened the chief business of the meeting, when the Fellows present proceeded to ballot for the President, Officers, and Council for the ensuing year. Scrutineers having been appointed, and the votes counted, the result was declared to be as follows:—President, Dr. Albert Günther, F.R.S.; Treasurer, Mr. Frank Crisp; Secretaries, Mr. B. Daydon Jackson and Prof. G. B. Howes. The President then delivered the annual presidential address, which, on the motion of Mr. C. B. Clarke, seconded by Prof. Stewart, it was resolved should be printed and circulated. The gold medal of the Society was formally awarded to Dr. J. G. Agardh, Emeritus Professor of Botany in the University of Lund, and, in consequence of his inability to receive it in person, was delivered on his behalf to his Excellency the Minister for Sweden and Norway, who made a suitable acknowledgment.

June 3.—Dr. A. Günther, F.R.S., President, in the chair.—Prof. G. B. Howes exhibited specimens of the remarkable Crustacean *Anaspides tasmaniæ*, from the Hartz Lake, Huon district, Tasmania, which he had received from Mr. G. M. Thomson, its discoverer (see *Trans. Linn. Soc.*, Zool. [2] vol. vi. p. 287), together with a letter stating that the animal is now known from three localities. He directed attention to a recent monograph by Calman (*Trans. R. Soc. Edinb.*, vol. xxxviii. p. 787), in which the conclusion was drawn that the "Pod Shrimps" of the genera *Acanthotelson*, *Gampsonyx*, and *Palæocaris*, in respect to characters in which they are anomalous, agree with *Anaspides*, and that the four genera are probably to be referred to an ancient group of primitive Malacostraca. He remarked that he was disposed to agree with Calman's determination of the morphological value of the "first thoracic segment" of Thomson, and that he could confirm his statement that the peduncle of the flagellum of the antenna was but two-jointed.—The Rev. T. R. Stebbing, F.R.S., threw doubts upon the association claimed by Calman for *Acanthotelson*, and remarked that some Amphipods are known to agree with *Anaspides* in the possession of double epipodial lamellæ. The "ocellus" of Calman did not appear to him to occupy the position of an ocellus, and he thought it might possibly be a luminous organ.—Dr. G. D. Haviland, F.L.S., gave the substance of a paper on *Termites*, illustrated by lantern-slides, showing some of the more characteristic and remarkable forms of nests made by these insects, as well as figures of the insects themselves. A discussion followed, in which Mr. Saville Kent, the Rev. T. R. Stebbing, and the Rev. F. C. Smith took part; Mr. Kent exhibiting another series of lantern-slides illustrating the nests of Australian species.—Prof. T. Rupert Jones, F.R.S., communicated a paper by himself and Mr. F. Chapman on the genus *Ramulina*, forming the second part of a paper of which the former portion, on the tubulose and fistulose Polymorphinæ, has been already published (*Linn. Soc. Journ.*, Zool. xxv. p. 496).—The Secretary communicated a paper, by Mr. E. C. Horrell, on the number of sterigmata and spores in *Agaricus campestris*.

June 17.—Dr. A. Günther, F.R.S., President, in the chair.—Dr. D. H. Scott, F.R.S., exhibited original preparations by Prof. Ikeno and Dr. Hirase, of Tokio, Japan, illustrating their discovery of spermatozoids in two Gymnospermous Phanerogams, namely, *Ginkgo biloba* and *Cycas revoluta* (*cf.* Bot. Centralblatt, Bd. lxix. Nos. 1-2, 1897, and Annals of Botany, June, 1897). The slides showed the spermatozoids while still in the pollen-tube, before the commencement of active movement. In the case of *Ginkgo* one section showed the two male generative cells, closely contiguous and enclosed in the pollen-tube. The general structure resembles that in many other conifers at the same stage, *e.g. Juniperus virginiana* and *Pinus silvestris* (Strasburger, Hist. Beiträge, iv. pl. 2). In *Ginkgo*, however, each generative cell showed a distinct spiral coil, situated in each cell, on the side remote from its neighbour. Another preparation of *Ginkgo* showed a series of sections across the micropyle, passing through a pollen-tube and its generative cells, the plane of section being in this case approximately parallel to the surface of contact of these two cells, through which four of the sections passed. In the two terminal sections of this series the spiral coil was clearly shown, consisting of about three windings. The spiral is connected with the nucleus of the cell, but whether it is itself of nuclear or cytoplasmic origin is not certain. In the preparation from *Cycas revoluta*, several pairs of generative cells were shown; in some cases the pollen-tube enclosing them was intact. The spiral coils in some of the generative cells were surprisingly clear, consisting of about four windings. A distinct striation was visible in connection with the coil, probably indicating the presence of the numerous cilia described by the Japanese discoverers. The facts admit of no other interpretation than that given by these authors, namely that in both *Ginkgo* and *Cycas* each generative cell gives rise to a spiral spermatozoid; the latter by its own movements (actually observed by Dr. Hirase in the case of *Ginkgo*) no doubt travels from the end of the pollen-tube to the female cell. In a discussion which followed on this highly important subject, Dr. W. T. Thiselton Dyer, C.M.G., Mr. W. Carruthers, F.R.S., Prof. E. Ray Lankester, F.R.S., Prof. Howes, F.R.S., and the President took part.—Mr. T. B. Blow exhibited and described a curious case of protective mimicry in *Asparagus albus*, which drew forth criticism by Mr. H. Groves and the President.—Mr. J. E. Harting exhibited and made remarks upon specimens of *Nestor productus* and *Nestor norfolcensis*, from the Derby Museum, Liverpool, lent for exhibition by Dr. H. O. Forbes. The specimen of *Nestor norfolcensis* was of especial interest, from the remark of Count Salvadori (Brit. Mus. Cat. Parrots, xx. p. 10) that this bird is now extinct and is only known from Latham's description (Gen. Hist. Birds, 1822, ii. p. 171), and from the description and figure of the head published by von Pelzeln (Sitzb. k. Akad. Wiss., 1860, xli. p. 322) from a drawing by Ferdinand Bauer, who had visited Norfolk Island where the bird was found. With regard to *Nestor productus*, it appeared (1) that the species underwent a change of plumage analogous to that of the Crossbills: (2) that the description given by Latham applied to a more adult bird than that now shown; (3) that the result of a comparison of the two skins exhibited and the dimensions of the wings, tarsi, and feet, rendered it doubtful whether the two forms were specifically distinct, the slight variations observable in the colouration being such as might reasonably be attributed to age or sex.—Mr. Miller Christy read a paper on *Primula elatior*, Jacq., in Britain. He remarked that this widely-distributed continental plant, though figured accidentally in "English Botany" in 1799, was not really detected in Britain till 1842, to which time the totally distinct hybrid Oxlip (*P. acaulis* × *veris*) was, by British botanists, confused with, and mistaken for it, as is still frequently the case. In Britain, *P. elatior* occupies a sharply defined area, divided by the valley of the Cam, with only two outlying localities, so far as Mr. Christy could ascertain. This area covers the two most elevated and unbroken portions of the boulder clay district, the loams and gravels of the river-valleys and the chalk being entirely avoided. The boundary-lines (some 175 miles in length) which had been traced by Mr. Christy with precision were, in consequence, very sinuous. They enclosed together about 470 square miles, over which area the Oxlip flourishes in immense abundance in all old woods and some meadows; while the Primrose (which grows all around) is entirely absent. Along the dividing line between the two, which is very sharply defined, hybrids are produced in great abundance. On the other hand, the Cowslip (which grows both around and throughout the Oxlip area) very rarely hybridises with it. Mr. Christy believed that the Primrose was, in this country, gradually hybridising the Oxlip out of existence. He then noticed a rare single-flowered variety of *P. elatior*, which he proposed to call var. *acaulis*, and several aberrations, showing upon the screen photographic views of these and of the hybrids, as well as a map of the distribution of the Oxlip in Britain. In a discussion which followed, Mr. C. B. Clarke, F.R.S., and Sir John Lubbock, Bart., M.P., confirmed the accuracy of Mr. Christy's observations.—On behalf of Mr. A. D. Michael, the Zoological Secretary read a report on the *Acari* collected by Mr. H. Fisher, naturalist of the Jackson-Harmsworth Polar Expedition, at Cape Flora, Northbrooke Island, Franz Josef Archipelago, in 1896. The collection had been formed under great difficulties, and consisted of five species, two of which (*Erethræus Harmsworthi* and *Oribata Fisheri*) were regarded as new to science.—Sir John Lubbock, Bart., M.P., F.R.S., communicated the substance of a paper entitled "Further observations on Stipules," in continuation of a former paper communicated by him to the Society on March 18 last.

The present paper, which was illustrated by diagrams, has reference, *inter alia*, to the Ash, Hop, and two species of Pea (*Lathyrus grandiflora* and *L. pratensis*). Mr. W. Carruthers, F.R.S., in commenting upon this paper, expressed the satisfaction which he was sure would be felt by botanists at the way in which the author was carefully working out details in the life-history of British plants, and in that respect conforming to the spirit of the charter of the Society which expressly defined the object of its formation to be "the cultivation of the science of natural history in all its branches, and more especially of the natural history of Great Britain and Ireland."—Prof. Conway Macmillan, of the University of Minnesota, communicated the principal points of a paper on minor tension-lines between plant-formations.

PARIS.

Academy of Sciences, June 28.—M. A. Chatin in the chair.—The President announced to the Academy the loss it had sustained by the death of M. Schützenberger, Member of the Chemical Section.—On the integration of the equation $\Delta u = F(u, x, y)$, by M. Émile Picard.—On uniform quadruply periodic functions of two variables, by M. Émile Picard.—On the rotatory parts of the transversal components of the velocity in a permanent flow gradually varied, by M. J. Boussinesq.—M. de Lapparent was nominated as Member in the Section of Mineralogy, in the place of the late M. Des Cloizeaux.—On psoriasis and its relations with syphilis, by M. F. Bouffé. The injection of orchitine appears to be specific as a cure for psoriasis. The latter frequently masks the symptoms of syphilis. In the cases cited, if the treatment had been sufficiently prolonged, there was no return of the disease.—On the treatment of cancer, and of several infectious diseases by ozone, by M. Charles Chardin.—On the causes of differences of quality in harmonic chords, by M. Bourcoud.—Observations on the sun, made at the Observatory of Lyons with the Brunner equatorial, during the first quarter of 1897, by M. J. Guillaume. A tabulated statement of observations on sun-spots and faculæ.—On the geodesic lines of oppositely curved surfaces, by M. Hadamard.—On the enumeration of primitive groups of which the degree is below 17, by M. J. A. Miller.—On the determination of the integrals of certain non-linear partial differential equations by their values on a closed surface, by M. E. Le Roy.—On the permanent deformations of metals, by M. G. A. Faurie.—Influence of the intensity upon the pitch of a sound, by M. André Broca. If the intensity of a sound decreases, the note goes up, even though the period of vibration remains the same. The effects are small, and in the experiments described amount to about $\frac{1}{5}$ of a tone.—Researches on nickel-steels. Magnetic properties and permanent deformations, by M. C. E. Guillaume. The effect of temperature upon the magnetic properties of the nickel-steels was first studied, and it was found that these alloys could be divided into two classes, those containing from 0 to 25 per cent of nickel, for which the effects produced by heat were irreversible, whilst in the second class, containing higher percentages of nickel, the effects were reversible. The permanent changes of length set up in these alloys are of the same order as those in the hard glass used in thermometers.—The sulpho-antimonites of silver, by M. Pouget. The salts KAg_2SbS_3 and Ag_3SbS_3 are described. K_2AgSbS_3 could not be prepared.—On the function of manganese in certain oxidations, by M. Ach. Livache. A discussion of the action of manganese salts in quick-drying oils.—The colour of the phosphorescence of strontium sulphide, by M. José Rodriguez Mourelo. The phosphorescence depends largely upon the nature of the impurities present, and hence upon the method of preparation. The sulphide produced by the action of sulphur upon strontianite at a red heat gives the finest green colour.—Observations on the molecular volumes of several crystallised carbohydrates at 0°, by M. Pionchon. An extension of an observation of Joule and Playfair to the effect that the molecular volumes of cane-sugar and milk-sugar were exactly equal to the volume occupied in the state of ice, of the water of which this mass contains the elements. The same relations hold approximately for xylose, glucose, levulose, mellitose and raffinose.—Trioxymethylene and paraformaldehyde, by M. Delépine. The heats of formation of trioxymethylene and paraformaldehyde from its elements were determined, and also the heat of solution of the former in water.—On some combinations of phenylhydrazine with metallic iodides, by M. J. Moitessier. The compounds $ZnI_2.2(C_6H_5.N_2H_3)$, $ZnI_2 5(C_6H_5.N_2H_3)$, $CdI_2.2(C_6H_5.N_2H_3)$, $MnI_2.2(C_6H_5.N_2H_3)$, and $NiI_2 6(C_6H_5.N_2H_3)$ are described.—On the combination of metallic salts with organic bases homologous with aniline and their isomers, by M. D. Tombeck.—On the action of acetylene on silver nitrate, by M. G. Arth.—On the tetrameric regeneration of the tarsus of the Phasmidia, by M. Edmond Bordage.—The *N'djembo* the caoutchouc plant of Fernan-Vaz, by M. Henri Jumelle. The plant is described and named *Landolphia Foreti*. It is distinguished from *Landolphia owariensis*, among other points, by the superior quality of the caoutchouc produced from it.—A new remedy against mildew and black rot, by M. Gaston Lavergne. The mixture proposed consists of copper sulphate (500 gr.), black soap (1000 gr.), and water (100 litres).—Observation on a French meteorite, the fall of which (at Clohars in 1822) was unnoticed, by M. Stanislas Meunier.—The nerves of the heart and thyroid gland, by M. E. de Cyon.—Researches on the ostioles of the mucous membranes, by M. J. J. Andeer.—Effects of a hailstorm, by M. A. Forel. This hailstorm of June 2, at Morges, was remarkable for the duration of the fall of hail, more than ten minutes; the great electrical disturbances, the lightning being almost continuous; the magnitude of the hailstones, 5 to 6 cm. in length; and the peculiar structure of some of the pieces of ice.

CONTENTS. PAGE

THURSDAY, JULY 15, 1897.

THE ANCIENT VOLCANOES OF BRITAIN.

The Ancient Volcanoes of Britain. By Sir Archibald Geikie, F.R.S., Director-General of the Geological Survey. Vol. I., pp. xxiv. + 477; Vol. II., pp. xvi. + 492. (London: Macmillan and Co., Ltd., 1897.)

THE Edinburgh school of geology, when of old it formulated the theory of existing causes of terrestrial change, established the fundamental principle of modern geological science. Thanks to this school, men learnt how rocks were formed, how the strata of the earth's crust were built up, how slow had been the evolution of the continents and oceans, and how important is the conception of time in regard to the past history of the globe. The brilliant representative of this illustrious school who has recently published a history of the volcanoes of Great Britain, sets forth in this remarkable treatise the great features in the volcanic history of the earth, and establishes the principles which will henceforth guide geologists in the study of the massive crystalline rocks.

From the remotest times there have existed on the surface of the globe volcanoes essentially similar to those now active. Such is the doctrine which Sir Archibald Geikie maintains. He has proved the uniformity of the phenomena and of the volcanic products throughout the geological past. He has indicated the cycles of differentiation among the magmas, and their recurrence in successive ages. He has shown how the sequence and structure of ancient eruptive rocks are to be determined.

The geological historian who shall hereafter record the stages in the progress of our knowledge regarding what may be termed fossil volcanoes, will attribute their first discovery to Guettard and Desmarest; their analysis to Sorby, to the German petrographers, and to Fouqué and Michel Lévy (to whom the present work is dedicated); and their synthesis to Sir Archibald Geikie, who has resuscitated and reconstructed the old dismantled volcanoes, buried under the geological formations of Great Britain.

The author, in a preface dealing with the history of discovery in the domain of volcanic geology, introduces his subject in the following sentences.

"In no department of science is the slow and chequered progress of investigation more conspicuous than in that branch of geology which treats of volcanoes. Although, from the earliest dawn of history, men had been familiar with the stupendous events of volcanic eruptions, they were singularly slow in recognising these phenomena as definite and important parts of the natural history of the earth. Even within the present century, the dominant geological school in Europe taught that volcanoes were mere accidents. A juster appreciation of the nature of the earth's interior was needed, before men could recognise that volcanic action had once been vigorous and prolonged in many countries, where no remains of volcanoes can now be seen."

"To France, belongs the merit of having laid the foundations of the systematic study of ancient volcanoes. As far back as the year 1752, Guettard recognised that the Puys of Auvergne were volcanic cones that had poured forth streams of lava. But it was reserved to Desmarest twelve years later to examine the question in detail, and to establish the investigation of former volcanic action upon a broad and firm basis of careful observation and sagacious inference. He discovered that the volcanoes of Central France were not all of one age, but had made their appearance in a long series, whereof the individual members became less perfect and distinct in proportion to their antiquity." "While these fruitful researches were in progress in France, others of hardly less moment were advancing in Scotland. Hutton, as a part of his immortal 'Theory of the Earth,' had conceived the idea that much molten material had been injected from below into the terrestrial crust, and he had found many proofs of such intrusion among the rocks of his native country. His observations, confirmed and extended by Playfair and Hall, and subsequently by Macculloch, opened up the investigation of the subterranean phases of ancient volcanic action" (Preface, pp. vii.-viii.).

From the peculiarly favourable structure of the country, Britain has been enabled to make many important contributions to the investigation of the subject. De la Beche, Murchison and Sedgwick led the way in recognising, even among the most ancient stratified formations of England and Wales, the records of contemporaneous volcanoes and their subterranean intrusions.

A new stage in the history of volcanic geology was entered when Sorby introduced the method of microscopic examination of rocks by means of thin slices. Petrographical investigation was thereby enabled to keep pace with stratigraphical research. The rocks of the whole globe have been made to pass through the German laboratories, and thus precise knowledge has been obtained regarding the mineralogical composition and structure of the rocks, and light has been thrown on the true principles of their classification. In France, Fouqué and Michel Lévy, studying volcanic rocks both in the field and in thin sections, have been able to reproduce the principal types artificially in their laboratory.

In Sir Archibald Geikie's volumes the study of ancient volcanic rocks now emerges from the laboratory, and is prosecuted under the broad sky among the crags, the shores, and the isles. Not that the minute description of internal structure or of chemical and mineralogical composition is neglected by him; but the rocks are no longer looked at as they are in themselves: their chief value is now sought in their association as parts of a connected volcanic history. A dyke is only noticed when its description allows it to be connected on the one side with a subterranean reservoir, and on the other with its superficial display of lavas or fragmental discharges. The rocks are studied as much from the point of view of their origin as from that of their composition, and their structure is shown to be in relation to some determinate part of a volcanic group. All that has been done, all that has been said in regard to these questions, will be found summed up in Sir Archibald's work, while his masterly exposition of the history of volcanoes from the earliest times down to our own day is enhanced with ingenious conclusions respecting the nature and causes of volcanic action.

The fossil volcanoes reveal no craters. No trace of their original cones has survived to our time, save in some exceptional cases where they have been entombed under lavas, or have been preserved under other accumulations. These and other characteristics con-

stitute difficulties in the study of ancient volcanic action. But they have not proved insuperable. Such has been the progress of this study, that it has already thrown light on the structure and mechanism of the active volcanoes of the present day. Thus a comparison of the pas with the present may enable us to arrive at some adequate conception of the nature and history of volcanoes in the geological history of the globe.

"In this research," as Sir Archibald Geikie remarks, "it is obvious that the presently active volcano must be the basis and starting-point of inquiry. At that channel of communication between the unknown inside and the familiar outside of our globe, we can watch what takes place in times of quiescence or of activity. We can there study each successive phase of an eruption, measure temperatures, photograph passing phenomena, collect gases and vapours, register the fall of ashes or the flow of lavas, and gather a vast body of facts regarding the materials that are ejected from the interior, and the manner of their emission.

"Indispensable as this information is for the comprehension of volcanic action, it obviously affords after all but a superficial glimpse of that action. We cannot see beyond the bottom of the crater. We cannot tell anything about the subterranean ducts, or how the molten and fragmental materials behave in them. All the underground mechanism of volcanoes is necessarily hidden from our eyes. But much of this concealed structure has been revealed in the case of ancient volcanic masses, which have been buried and afterwards upraised and laid bare by denudation.

"In yet another important aspect modern volcanoes do not permit us to obtain full knowledge of the subject. The terrestrial vents, from which we derive our information, by no means represent all the existing points of direct connection between the interior and the exterior of the planet. We know that some volcanic eruptions occur under the sea, and doubtless vast numbers more take place there of which we know nothing. But the conditions under which these submarine discharges are effected, the behaviour of the outflowing lava under a body of oceanic water, and the part played by fragmentary materials in the explosions, can only be surmised. Now and then a submarine volcano pushes its summit above the sea-level, and allows its operations to be seen, but in so doing it becomes practically a terrestrial volcano, and the peculiar submarine phenomena are still effectually concealed from observation.

"The volcanic records of former geological periods, however, are in large measure those of eruptions under the sea. In studying them we are permitted, as it were, to explore the sea-bottom. We can trace how sheets of coral and groves of crinoids were buried under showers of ashes and stones, and how the ooze and silt of the sea-floor were overspread with streams of lava. We are thus, in some degree, enabled to realise what must now happen over many parts of the bed of the existing ocean.

"The geologist who undertakes an investigation into the history of volcanic action within the area of the British Isles during past time, with a view to the better comprehension of this department of terrestrial physics, finds himself in a situation of peculiar advantage. Probably no region on the face of the globe is better fitted than these islands to furnish a large and varied body of evidence regarding the progress of volcanic energy in former ages" (vol. i. pp. 5–6).

Towards the close of his second volume, after adducing in full detail the volcanic records of his native country, the author remarks that

"A review of the geological history of Britain cannot but impress the geologist with a conviction of the essential uniformity of volcanism in its manifestations since the early beginnings of geological time. The composition and structure of the materials erupted from the interior have remained with but little change. The manner in which these materials have been discharged has likewise persisted from the remotest periods. The three modern types of Vesuvian cones, Puys and fissure-eruptions, can be seen to have played their parts in the past as they do to-day."

After an introductory series of chapters dealing with general principles of investigation and interpretation, the work enters upon a detailed description of the volcanic phenomena of the successive geological periods, beginning with the most ancient.

"Among the earliest igneous masses of which the relative geological date can be fixed are the dykes which form so striking a system among the Archæan rocks of the north-west of Scotland, and show how far back the modern type of volcanic fissures and dykes can be traced. No relic, indeed, has survived of any lavas that may have flowed out from these ancient fissures, but so far as regards underground structure, the type is essentially the same as that of the Tertiary and modern Icelandic lava-fields" (vol. ii. pp. 470–471).

The early Palæozoic volcanoes formed cones of lava and tuff comparable to those of such vents as Vesuvius and Etna. As illustrations of the Vesuvian type in the volcanic history of Britain, the author refers to the great Lower Silurian Volcanoes of Cader Idris, Arenig, Snowdon and the Lake District, and to the Old Red Sandstone volcanoes of Central Scotland. In the Lake District the pile of material ejected during Lower Silurian time was at least 8000 or 9000 feet thick. In the Old Red Sandstone basins of Central Scotland there were more than one mass of lavas and tuffs thicker than those of Vesuvius.

The Carboniferous volcanoes were not only abundant and persistent in Scotland, but they attained there a variety and development which give their remains an altogether exceptional interest in the study of volcanic geology. They are referable, from their characters and their age, to two different types, *Plateaux* and *Puys* (vol. i. p. 364).

In the *Plateau-type*, the volcanic materials were discharged over wide tracts of country, so that they now form broad tablelands or ranges of hills, reaching sometimes an extent of many hundreds of square miles and a thickness of more than 1000 feet. Plateaux of this character occur within the British area only in Scotland where they are the predominant phase of volcanic intercalations in the Carboniferous system, and are eminently characteristic of the earliest portion of that period. This *Plateau* or *Fissure-type* is, among modern volcanoes, best developed in Iceland. In that island, during a volcanic eruption, the ground is rent open by long parallel fissures, only a few feet or yards in width, but traceable sometimes for many miles, and descending to an unknown depth into the interior. From these fissures lava issues—in some cases flowing out tranquilly in broad streams from either side, in other cases issuing with the discharge of slags and blocks of lava which are piled up into small cones set closely together along the line of the rent. By successive discharges of lava from fissures, or from vents opening on lines of fissure, wide plains may be covered with a floor of rock made up of horizontal beds.

The author shows that, after the beginning of the Carboniferous Limestone period, when eruptions of the

plateau-type had generally ceased, volcanic activity showed itself over the area of the British Isles in a different guise, both as regards the nature of its products and the manner and scale of their discharge (vol. i. p. 414). Instead of widely extended lava-sheets and tuffs, piled above each other sometimes to a thickness of many hundred feet, and stretching over hundreds of square miles, another phase of volcanism presented itself, where scattered groups and rows of *Puys*, or small volcanic cones, threw out, in most instances, merely tuffs, and these often only in trifling quantity, though here and there their vents also poured forth lavas, and gradually piled up volcanic ridges which, in a few cases, almost rivalled some of the plateaux. The evidence for these less vigorous manifestations of volcanic activity is furnished (1) by layers of tuff and sheets of basaltic-lavas intercalated among the strata that were being deposited at the time of the eruptions; (2) by necks of tuff, agglomerate, or different lava-form rocks that mark the positions of the orifices of discharge; and (3) by sills, bosses, and dykes that indicate the subterranean efforts of the volcanoes. The comparatively small thickness of the accumulations usually formed by these vents, heir extremely local character, the numerous distinct horizons on which they appear, and the intimate way in which they mingle and alternate with the ordinary Carboniferous strata, are features which at once arrest the attention of the geologist, presenting, as they do, so striking a contrast to those of the plateaux.

In a vast number of ancient volcanic vents, no trace can be discovered of their connection with any fissure in the earth's crust (vol. i. p. 53). Such fissures may, indeed, exist underneath, and may have served as passages for the ascent of lava to within a greater or less distance from the surface. But it is established in these volumes that volcanic energy has the power of blowing out an opening for itself through the upper part of the crust without the existence of any visible fissure there. What may be the limits of depth at which this mode of communication with the outer air is possible we do not yet know. They must obviously vary greatly according to the structure of the terrestrial crust on the one hand, and the amount and persistence of volcanic energy on the other. But where the thickness of rock above the end of the fissure is not too great, the expansive energy of the vapours absorbed in the magma may overcome the resistance of that cover, and blow out an orifice by which the volcanic materials can reach the surface. In an ordinary volcanic orifice the ground-plan of the neck is usually irregularly circular or elliptical.

The discharge of explosive vapours was sometimes the first and only effort of volcanic energy. Generally, however, fragmentary volcanic materials were ejected, and cones of tuff were formed; or, if the eruption was more vigorous, lava was poured out. Towards the close of a volcanic period, the vents were gradually choked up with the fragmentary materials that were ejected from, and fell back into them. When the vents were plugged up by the consolidation of fragmentary matter, or the uprise of lava in them, the final efforts of the volcanoes led to the intrusion of *sills* and *dykes*, not only into the rocks beneath the volcanic sheets, but also, in many instances, into at least the older parts of these sheets themselves. The size and extent of the *sills* may thus be a record of the intensity of this latest phase of the volcanic eruptions.

The chief products of the Carboniferous volcanoes are basic rocks, dolerites, and basalts, with andesites; they are somewhat more acid in the necks, where are found diabases, trachytes, and phonolites. The Puy lavas are generally more basic than the lavas of the plateaux.

The Permian volcanoes were the last of the long Palæozoic series, and, so far as we yet know, the whole of the Mesozoic periods, within the area of Britain, were absolutely unbroken by a single volcanic eruption. It was an era of geological calm, during which the Triassic, Jurassic and Cretaceous formations were slowly accumulated over the larger part of Europe. The stratigraphical quietude was not, indeed, unbroken. The widespread subsidence of the sea-bottom was interrupted here and there by important upheavals, and considerable geographical changes were in process of time accomplished. But, save in one or two widely separated areas of Europe, there were no active volcanoes over the whole continent.

After the enormous interval represented by the whole of the Mesozoic and the earlier part of the Tertiary formations, a time of disturbance arose once more, and a surface of 40,000 square miles was covered in the north-west of Britain by great basalt-floods. The whole of these latest volcanic manifestations were comprised within the earlier (Oligocene and, perhaps, early Miocene) part of older Tertiary time.

The first indications of Tertiary volcanic energy in the north-west of Europe were displayed in the formation of numerous parallel fissures extending in the British Isles in a general north-westerly direction. Between the walls of these opened fissures a basic magma rose and solidified, thus constituting the innumerable dykes of the region. Sometimes the magma reached the surface of the ground, and streaming forth there formed the successive sheets of basalt in the great plateaux. In some instances, as in modern Icelandic eruptions, the lava may have issued immediately from the fissures; in others its rise has been accompanied with the formation of small cones along the line of a chasm. During a tolerably protracted period, basic and intermediate lavas (basalts, dolerites, andesites, and trachytes) continued to be poured out, together with possibly an occasional outflow of rhyolite. These eruptions took place from many points, and not from great central volcanoes like Vesuvius. The result of their operations was to bury under more than 3000 feet of volcanic materials the broad valley between the mainland of Scotland and the chain of the Outer Hebrides. This long series of eruptions is shown to have been subaerial by the terrestrial relics—plants, insects, river-beds and lake-bottoms preserved under and between the lavas. Gradually, as the pile of volcanic material grew in thickness, the magma was less frequently ejected to the surface, but it insinuated itself underneath to form there sills or intrusive sheets.

The second stage in the Tertiary volcanic history is revealed by the great bodies of amorphous and banded gabbro which form so prominent a feature in the Inner Hebrides. These eruptive masses have disrupted the

lavas of the plateaux which are more or less metamorphosed around them, and are traversed by a fringe of finer-grained sills and veins of dolerite, gabbro, troctolite, picrite, &c., which have often insinuated themselves between the sheets of the plateau-basalts. The coarse-grained and banded gabbros may have consolidated at some depth; at least nothing is yet certainly known of their superficial equivalents.

The third stage of activity, probably long posterior to the second, likewise furnishes no evidence of any superficial ejection. It is recorded by a series of markedly acid rocks—obsidians, felsites, rhyolites, porphyries, granophyres, and granites. These rocks form huge conical hills, which in outward aspect recall the trachytic Puys of Auvergne. They traverse alike the plateau-basalts and the bosses of gabbro, into which they send many dykes and veins. They also project numerous thick sills into the formations lying underneath. The rocks around these acid protrusions have been greatly metamorphosed, while the granophyres and granites have in turn undergone considerable change in composition from having caught up and assimilated sometimes a fourth of their bulk of basalt or gabbro.

After the uprise of the granophyres with their surrounding network of felsitic dykes and veins, a new ascent of basic material manifested itself, recalling that of the earliest basalt-dykes, but on a minor scale. The dykes then formed cut all the other members of the volcanic series, including the granophyres. No trace remains of any superficial discharges connected with these latest dykes. If they ever gave rise to outflows of lava, these have long since disappeared in the vast denudation which the Tertiary volcanic rocks have undergone.

The latest eruptions of North-Western Europe, forming the Tertiary volcanic series, are shown by Sir Archibald Geikie to have far exceeded in area, and possibly also in bulk of material discharged, all the eruptions that had preceded them in the geological record.

We learn further that neither in their forms or products, nor by their extent and vigour, did the volcanic manifestations of the successive ages of the geological past materially differ from those of the present time. There is assuredly no evidence that volcanic energy has gradually waned since the dawn of geological history.

A consideration of the distribution of the volcanic rocks in time shows not only how singularly uniform the course of volcanic activity has been, but that there is no evidence of the cessation of any of the broader petrographical types during geological history. Quite as much variety may be observed among the erupted materials of Tertiary time in Britain as among those of the early ages, when the earth was younger and its volcanic vigour might be supposed to have been greater and more varied than it is now.

From the evidence detailed in these volumes, it appears that the sequence from basic to acid discharges was on the whole characteristic of each eruptive period. It is obvious however, the author observes, that as the protrusions of successive periods took place within the same limited geographical area, the internal magma during the interval between two such periods must in some way have been renewed as regards its constitution, for when, after long quiescence, eruptions began once more, basic lavas appeared first, and were eventually followed by acid kinds.

Various opinions have been propounded as to the cause or causes of the differentiation observable in erupted masses, but none of them are entirely satisfactory. We must await the results of further exploration in the field and of continued research in the laboratory.

What appears to have taken place within a subterranean molten magma which has been propelled into the earth's crust as a boss or laccolite, with or without a connected system of dykes, may possibly be made to throw some light on the remarkable changes in the characters of lavas successively erupted from the same vent during the continuance of a volcanic cycle. Whether or not any such process of differentiation can be proved to take place within a subterranean volcanic reservoir, the sequence of erupted lavas bears a curious resemblance to the order in which the constituents of some large bosses succeed each other from margin to centre (vol. i. p. 92).

Sir Archibald Geikie has written the history of the ancient volcanoes of Britain in a series of attractive chapters, which he has illustrated with more than four hundred sketches, photographs and maps. But the fine work with which he has enriched science is much more than a detailed description of the crystalline rocks of his own country. He elucidates their structure and arrangement,.and explains thereby their history. He rises from a consideration of facts to a discussion of the cause of volcanic phenomena. He makes the extinct volcanoes bear their testimony in favour of the uniformity and unity of the laws of nature. His work will remain one of the monuments of our time, establishing for the future the conception of the continuity of volcanic phenomena from the earliest periods, and, so far as the geological records go, demonstrating that the interior of our planet has reacted on its exterior in the same way and with the same results. CHAS. BARROIS.

AMERICAN MATHEMATICS.

Higher Mathematics: a Text-book for Classical and Engineering Colleges. Edited by Mansfield Merriman and Robert S. Woodward. Pp. xi + 576. (New York: John Wiley and Sons. London: Chapman and Hall, Ltd., 1896.)

THIS is a style of mathematical treatise to which we are not accustomed in this country, from the luxury of the print and size of page, as well as for the refreshing novelty and interest of the contents.

Till recently, it was thought that the study of mathematics was not likely to flourish in America, as *trop vieux jeu* by the side of the new physical and biological sciences. To-day, however, it is the American student who is the most enthusiastic follower of recent mathematical development, while we in this country are being left far behind.

The words on the title-page—A Text-book for Classical and Engineering Colleges—the equivalent of our own—For Schools and Colleges—is not, however, taken, as with us, to be the rendering of *In usum Delphini;* all human interest arising from the application of theory has not been carefully eliminated from the pages, as

likely to confuse or excite the mind of the student; on the contrary, the various contributors insert carefully chosen appropriate illustrations as the best means of elucidating the difficulties of the abstract theory. With us the spirit of the schoolmaster is too much abroad in our mathematical writings; it has even been objected that these illustrations tend to obscure a subject, as it were, with the smoke of its own guns: a musty simile in these days of smokeless gunpowder.

Thus, for instance, the solution of a quintic equation is presented as required for the determination of the supply of a water-main (p. 13); very vulgar this, our college professor will say. So, too, the intuitive reasoning of a graphical procedure with an appropriate diagram has been freely employed to replace the tedious and unconvincing procession of formulas which impede the progress of our own students. A mention of M. Félix Lucas's electrical determination of the roots, real and imaginary, might well have found a place here.

Each of the eleven chapters of the book is undertaken by a different writer—Chapter i., on the Solution of Equations, by Mansfield Merriman; and Chapter ii., on Determinants, by Laenas Gifford Weld; both complete and original in their way.

The treatment, in Chapter iii., of Projective Geometry, by George Bruce Halsted, is very bright and stimulating; this is a subject ignored in our own mathematical curriculum.

The two forms of spelling "centre" and "center," appear on the same page (95); the second is, of course, phonetically correct, as the English pronunciation always inverts the liquid and the vowel in the French spelling, here and in all similar words.

Chapter iv. is on Hyperbolic Functions, by James McMahon. Our scholastics look upon this subject as a temporary fad, which has not come to stay; however, electricians find them indispensable, and many elegant electrical applications, among others equally important, of mechanical and astronomical interest, such as catenaries, loxodromes, charts, conjugate functions, will be found collected here.

The long form of these functions, cosh, sinh, tanh, . . . has been retained, with a suggestion that the ugly sounds they suggest should be avoided by pronouncing them *h*-cosine, *h*-sine, *h*-tangent, &c. But the modern continental practice is to abbreviate the symbols to ch, sh, th, pronouncing only the letters *c-h*, *s-h*, *t-h*, as with the Elliptic Functions; so also for their inverse functions, ch^{-1}, sh^{-1}, th^{-1}, employed here, for their obvious advantages in integration. A well-arranged table concludes this chapter; we miss, however, Bernoulli's numbers in their proper place in the expression of $\tan x$, $\mathrm{th}\, x$. . . .

Prof. Byerley, of Harvard, contributes Chapter v., on Harmonic Functions. When his genial treatise on Fourier's Series and Harmonic Analysis made its appearance, some four years ago, it was welcomed by all physicists as the long-desired manual, which placed this subject before them in an intelligible manner, devoid of artificial obstacles and impediments. Unfortunately the treatise fell into the hands of mathematical critics, who could see little merit in the book, because it passed over in silence the tedious, and useless, arguments concerning the legitimacy of the expansions. If an electrician is to employ a Fourier Series, he will content himself with the first two or three terms of the series; just as the calculator of mathematical tables will not, for practical purposes, employ more than three, or four terms at most, in Taylor's Series. But where the applicability becomes doubtful, by reason of the neighbourhood of a discontinuity, he will assure himself, by a diagram such as those on p. 199, of the limits of the divergence.

These difficulties concerning the discontinuity of functions is very properly relegated to another chapter, number vii., on Functions of Complex Variables, by Thomas S. Fiske, which gives us a very clear account of the most recent manner, of the school of Weierstrass, of approaching such refinements of argument. We are pleased to find the name "one-valued function" instead of "uniform function," which is misleading to the beginner.

Prof. Woolsey Johnson, of the U.S. Naval Academy, contributes Chapter vii., on Differential Equations. His own formal treatise on the subject is well known and highly popular; and the present chapter incorporates the essential, or what Maxwell called the "gentlemanly," knowledge of the subject.

The next two chapters—Chapter viii., on Grassmann's Space Analysis, by Edward W. Hyde, and Chapter ix., on Vector Analysis and Quaternions, by Alexander Macfarlane—seem to us by comparison to be of the nature of luxuries, appealing to the purely analytical spirit; although even here electrical applications are introduced to show how the theories may be usefully applied.

Chapter x. is a short and useful *résumé*, by R. S. Woodward, of the principal parts of Probability and the Method of Least Squares, with which every physical student should now be familiar; and the volume concludes with Chapter xi., on the History of Modern Mathematics, by David Eugene Smith, in which the author is compelled to apologise for the incompleteness imposed upon him by the exigencies of room, but which, nevertheless, provides the most important details required for reference.

The account given by the Editors, in the preface, of the work expected of the average American student, shows that the standard of requirement is much higher than in this country, and not hampered by traditional prejudice.

A. G. GREENHILL.

OSTEOLOGY.

The Vertebrate Skeleton. By Sidney H. Reynolds, M.A. Pp. xvi + 559. (Cambridge: University Press, 1897.)

THIS most recent addition to the Biological Series of the Cambridge Natural Science Manuals edited by Mr. A. E. Shipley, is an attractive-looking volume, well printed, and with the monotony of the text agreeably broken by a judicious use of small capitals, italics, and clarendon type. The numerous illustrations, which are probably accountable for the high price (12*s.* 6*d.*) of the book, though simple in execution are clear in detail, and, on the whole, chosen with discretion. The majority of the figures have not been published before, and are based on specimens contained in the Cambridge University Museum and the Natural History Museum, London. The text is remarkably free from typographical errors, but is frequently bald in style and irritating from

unnecessary iteration. This repetition, it is true, is apologised for in the preface, but it could have been avoided by altering the plan of the book, which as it stands is rather confusing.

What strikes one most on glancing through the pages is the disproportionate treatment of the subject. To devote one-third of the whole book to the mammalian skeleton shows that the author has allowed himself a free hand where the facilities for compilation are greatest—and his indebtedness to the "Osteology of the Mammalia" is admitted in the preface. Where, however, it has been necessary to collect the detailed statements from scattered sources, as, for instance, in Fishes and Amphibia, the results are very far from satisfactory. The parts relating to the Cyclostomi, Ganoid fishes, the shoulder-girdle of Anura, and the hyoid of Reptilia are especially poor. The classificatory scheme (pp. 30-49), including as it does extinct as well as living vertebrates, should prove of considerable service to the student. It is well up to date, and, on the whole, trustworthy, although ichthyologists will probably gird at the inclusion of a physoclistous form like *Exocœtus* among the Clupeidæ. It would have been well if the generic and specific names of the borrowed figures had been checked by reference to some modern catalogue, instead of relying so implicitly upon those used by the original authors. *Galeus*, for instance (Fig. 15), should read *Galeocerdo*, and *Docidophryne gigantea* (Fig. 30), *Bufo marinus*; while the Figs. 16 and 17 of the seven-gilled shark should, in the student's interests, be given the same generic name, either *Notidanus* or *Heptanchus*. The specimen in the Natural History Museum, on which Fig. 16 is based, is marked *Notidanus*, while Gegenbaur's figure, which is reproduced in Fig. 17, is labelled *Heptanchus*, and Mr. Reynolds has, regardless of uniformity, adopted the two names as he found them.

The want of cohesion throughout the text detracts seriously from the value of the book. The various sections, culled from different sources, are not blended together, so that the product is indigestible and difficult of assimilation. The failure to treat the subject from a consistent morphological point of view is, in fact, the great flaw in the book. Positive inaccuracies are not common, but the sternum ought not to come under the head "Hyoid apparatus" (p. 162), the epipubic cartilage of *Xenopus* (p. 188) and the horny beaks of *Siren* (p. 168) are not "minute," and auditory ossicles are not as large as Fig. 100 would lead one to believe. The application of the name "branchiostegal rays" to the endoskeletal cartilages of the branchial septum of selachians (p. 120) implies a false homology with the dermal bones attached to the hyoid arch in bony fishes, while the inclusion of the vomer of the dog (p. 395), under the head "Bones in relation to the Olfactory Capsules," fails to impress upon the student the fact that this bone is morphologically an ossification of the mucous membrane of the roof of the mouth.

That great credit is due to Mr. Reynolds for his conscientious industry and honesty of purpose there is abundant internal evidence to show, but the product of his labours is—a book which is just good enough to suggest how valuable it might have been had its compilation been entrusted to a qualified morphologist. At the same time, Mr. Reynolds is to be congratulated on the large amount of information which he has brought together, and on the fact that he has not neglected the extinct forms. And although, in its present form, the book cannot with advantage be used as a book of reference, while its abrupt and disconnected style renders it ill-adapted for continuous reading, there can be litt doubt that if, when a second edition is called for, the plan of the book were simplified, the inaccuracies corrected, and the various chapters and sections connected up and coordinated, the book would prove a valuable addition to the student's library.

OUR BOOK SHELF.

Studien über Dampfspannkraftmessungen. By Georg W. A. Kahlbaum; with the co-operation of C. G. von Wirkner and others. Part ii. 1st half. Pp. x + 221. (Basel: Benno Schwabe, 1897.)

IN the first part of this work (NATURE, March 8, 1894, p. 436), measurements of the vapour pressures of a number of substances were given. The method used in the determinations was also fully described, and its accuracy discussed. The author's intention was to devote the second part of the book to a discussion of the theoretical bearing of the experimental material collected: Further experiments with substances belonging to chemical groups other than those previously examined revealed, however, the necessity of first enlarging this experimental material; the present volume contains the results of these additional measurements. The experimental method employed is the same as before, and the results are given in the form of numerical tables and of curves. Every precaution appears to have been taken to secure accuracy. Where previous observations exist, the results are compared together, and the satisfactory agreement found between the results obtained by Ramsay and Young, for example, by the statical, and by the authors by the dynamical method, may be regarded as further evidence of the trustworthiness of the latter. In this volume the measurements extend from about 0 to 760 mm., except in cases where the solidification of the substance prevented the measurements at lower pressures. The substances for which new experimental results are given are benzene, brom-benzene, benzaldehyde, phenol, aniline, benzonitrile, benzyl alcohol, nitrobenzene, benzoic acid, ethyl alcohol, propionic, normal butyric, valeric, heptylic, isobutyric and isocaproic acids, methyl-, dimethyl-, ethyl- and diethyl-aniline, phenylmethyl ketone, methyl benzoate and benzoyl chloride.

In connection with the fatty acids, the accuracy of Dühring's rule is discussed. The rule states that the difference between the boiling-points of a liquid at some standard pressure and at any other pressure divided by the corresponding difference for some other liquid is a constant quantity for that pair of liquids. This, it appears, is sufficiently accurate only when the liquids belong to a group of closely related substances, such as the fatty acids.

In conclusion, it is hardly necessary to point out the great value, scientific and practical, of careful determinations, such as those before us, of the vapour pressures of liquids.

The Induction Coil in Practical Work, including Röntgen Rays. By Lewis Wright. Pp. vi + 172. (London: Macmillan and Co., Ltd., 1897.)

THE discovery of the Röntgen rays has created a revived interest in many of the beautiful experiments that can be performed with the aid of the Ruhmkorff induction coil, and is thus indirectly a sufficient justification for the appearance of this treatise of 172 pages. More especially

written for those who, without much previous acquaintance with electrical apparatus, are for purposes of practical utility or scientific recreation anxious for theoretical and practical knowledge on the subject, this little book is also replete with useful information and suggestive hints that will not fail to prove of service to more experienced electricians. The volume is methodically arranged and well illustrated; and if there are omissions which might with advantage have been supplied, these are no doubt largely due to the author having been confined to a limited amount of space. So many experiments connected with the electrical discharge in rarefied and dense gases can be performed not only with an induction coil, but equally efficiently with a Wimshurst or other form of electrostatic influence machine, that one cannot but regret that the author has so rigidly confined himself to the application of coils alone. For a similar reason, it seems a pity not to have included some detailed information as to the so-called high frequency coils of Tesla and Elihu Thomson, which, even as an adjunct to induction coils, are not quite so completely abandoned for X-ray work as the author appears to imagine, while they afford a means for many other instructive experiments of comparative novelty and great beauty. It is necessary to say, moreover, that the brief references that do appear in the book to such coils, as also to the use of alternating currents generally, are scarcely as accurate and as lucid as might be desired.

It is to be regretted that the author uses the word *current* in a loose and, sometimes, in a very misleading manner. Notwithstanding these defects, which it is to be hoped the author may be able to remedy in subsequent editions, the book is undoubtedly the best popular and practical work that has yet appeared on the subject of which it treats.

The Calculus for Engineers and Physicists. By Prof. Robert H. Smith. Pp. xi + 176. (London: Charles Griffin and Co., Ltd., 1897.)

NOT only is "Integration more useful than Differentiation," the author's opening statement, but the conception of Integration is more tangible and easy to grasp than that of Differentiation, a far more abstract idea.

We recognise the growth of a tree after a few years, although the actual rate of growth is infinitesimal.

For purposes of application, a knowledge of Differentiation must just precede the inverse operation of Integration; but that does not justify our present system of carrying the student through the Differential Calculus before starting on the Integral; the two subjects should be carried out, as far as possible, *pari passu*.

Classified Reference Tables of Integrals form a feature of this work; and the author has also touched upon the useful portions of Differential Equations.

Any analytical difficulty is explained preferably by means of a careful diagram (as might be expected from an author of Graphical Calculus), and by intuitive reasoning, rather than by processions of unconvincing equations and inequalties, employed by schoolmen of the pure orthodox mathematical faith; whose indulgence the author begs in his Preface, asking them to remember that there is arising a rapidly increasing army of men eagerly engaged in the development of physical research, . . . whose mental facilities have been wholly trained by continuous contact with the hard facts of sentient experience, and who find great difficulty in giving faith to any doctrine which lays its basis outside the limits of their experiential knowledge. G.

Zur Zoogeographie der landbewohnenden Wirbellosen. Von Dr. Otto Stoll. Pp. 113. (Berlin: Friedländer, 1897.)

THE majority of treatises upon geographical distribution have used as facts and framed their conclusions upon the range of vertebrated animals only. A few manuals, such as M. Trouessart's excellent book, and Mr. Beddard's "Text-book of Zoogeography" in the Cambridge series of scientific handbooks, have attempted a rather wider survey of the facts of the science, the necessity for which is emphasised by the short essay now before us. The main object of the science of geographical distribution is clearly, we take it, to state the facts; but it is illogical to avail oneself merely of a selected series of facts. This is particularly evident in view of another aspect of the science; for some of its more important inferences deal with the former changes in the relative position of oceans and continents. Birds and mammals being comparatively modern creations, can throw no light upon more distant changes of this kind; and facts drawn from those groups are by no means sufficient to serve as a basis for the view, now so generally becoming accepted, that there was in earlier times a vaster antarctic continent than the shrunken remnant now existing. Dr. Stoll strongly supports this notion, and it is from invertebrate groups that arguments are to be drawn. He is, moreover, against the theory of polar dispersal, which by its ingenuity, if for no other reason, has commanded much attention. Dr. Stoll clearly shows the importance of a consideration of invertebrates in discussing the inferences of geographical distribution, and we could have wished that his little brochure of only 113 pages had been more expanded.

Transactions of the American Microscopical Society. Edited by the Secretary. Vol. xviii. Pp. 413. (Buffalo, N.Y.: A. T. Brown, 1896.)

THIS report of the proceedings of the American Microscopical Society at the nineteenth annual meeting, held at Pittsburg in August of last year, is a very creditable publication. Many of the papers are distinctly valuable contributions to science, and the plates which illustrate them are of a high standard of excellence. Among the subjects and authors are the following:—Notes on comparative histology of blood and muscle, by Miss Edith J. Claypole; the character of the epithelium of the peritoneum of the tailed amphibia of the Cayuga lake basin, by Miss I. M. Green; several interesting papers on photomicrography, and on water supply; the red blood corpuscle in legal medicine, by Dr. M. C. White (accompanying this paper are some fine photo-engravings of blood corpuscles of man and various animals, magnified × 10,850, 2560, 840, and 640 diameters); yeasts and their relation to malignant tumours, by Dr. A. R. Defendorf; the bacteriology of diphtheria, by Dr. C. F. Craig; and an instructive address by the President, Dr. A. Clifford Mercer, on the effect of aperture as a factor in microscopic vision.

Experimental-Untersuchungen über Elektricität von Michael Faraday. No. 86, Series iii. to v., pp. 103; No. 87, Series vi. to viii., pp. 179. Edited by A. J. v. Oettingen. (Leipzig: Wilhelm Engelmann, 1897.)

THESE two volumes are the latest additions to Prof. Ostwald's renowned "Klassiker der exakten Wissenschaften"—a series of edited translations and reprints which has no rival. They contain translations of papers read by Faraday before the Royal Society in 1833–4, upon his electrical researches, the translations being from the *Philosophical Transactions* of those years. A few explanatory notes are added by the editor, Dr. A. J. v Oettingen.

Complaints are often made of the neglect of foreign scientific literature by German investigators, but it should be remembered at the same time that we have no series of translations of scientific classics to compare with the one in which the two present volumes appear.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Fullerian Professorship of Physiology at the Royal Institution.

I AM writing in the assurance that my letter will or will not appear in your columns, according as you shall have judged whether or no it deals with public matter. And this again depends upon the degree in which the Royal Institution of Great Britain is regarded as fulfilling a public function.

Briefly, the facts are these:—

I hold the "Fullerian Professorship of Physiology and Comparative Anatomy" at the Royal Institution. I am surprised and disappointed to find that the duties of that post are regarded in a very flimsy light, and that no provision can be made, either in the Institution itself or in the adjoining Davy-Faraday Laboratory towards their more adequate performance. The obvious fact that the lecture-room rests upon the laboratory, acted upon with such admirable effect in the case of physics and chemistry, is altogether ignored in the case of physiology, with the result that the instruction that can be offered to the public in this latter subject is deficient or inferior, and—in the bad sense of these words—popular and literary. The very excellence of the lecture-theatre, together with the absence of any work-room, diverts the activity of the chair into other than its proper channels.

The Royal Institution of Great Britain, although it arose by private enterprise, has now for many years occupied the place of a public organ of natural knowledge, and its title expresses its *de facto* relation to the educated public, who look to the Royal Institution for the best information that can be given in the various subjects there dealt with.

It is a matter for regret—indeed in the present state of ignorance of physiology, which by many otherwise well-informed persons is supposed to be synonymous with vivisection—it is an actual misfortune, that the Fullerian Professors of Physiology are not enabled to give to the Institution the best work of which they may be capable. To profess "physiology" of an inferior character, under the auspices of the Royal Institution of Great Britain, is misleading and injurious to the interests of science.

I have felt some hesitation before requesting you to publish this letter, but can see no other means of testing the correctness of my opinion as to what is due to the public at the Royal Institution of Great Britain by the channel of its Fullerian Professorship of Physiology. AUGUSTUS D. WALLER.

Streaming Movements of the Protoplasm in Pollen of Flowers.

IT may, perhaps, not be generally known that pollen of flowers affords a convenient example of the circulation of protoplasm. If pollen from a fox-glove be placed in a solution of sugar at ordinary temperature in a drop-slide, the grains sprout within twenty minutes, and grow during several hours at an average rate of 1/10 millimetre per hour. The granules of protoplasm move in opposite streams side by side, turning at the lower end of the tube and inside the grain; the rate of motion may be calculated at 1 millimetre in one and a half to two minutes. The rapidity and duration of the streaming movement vary in different species; in the pollen of the fox-glove it seldom continues longer than five or six hours, but in that of the bee orchis it may be still observed on the third day, after the tubes have ceased to grow. Protoplasm which has been set free by the bursting of tubes or grains, continues to show signs of life for a longer period. The granular character of the protoplasm is less distinct in some species than in others, but with a sufficiently high power—1/8—a visible motion of the contents of pollen tubes appears to be common. H. B. POTTER.

July 13.

Sensitiveness of the Retina to X-Rays.

WHILE trying a few days ago to detect the position of a coin which a child had swallowed, I found that the retina is affected by the X-rays. I have since learnt that this observation is not new, but my method of work may be of interest. For the purpose of the coin experiment the tube of the usual Jackson type was placed immediately under a table of 1-inch deal in a dark room; on bringing my eye close to that part of the table where a phosphorescent screen showed the most intense radiation, after I had been in the dark for at least ten minutes, I could perceive a faint illumination of the retina, and on moving small metal objects to and fro immediately in front of the eye, I could see their shadows on the retina appearing to move always in the opposite direction. On moving the eye further away from the object the shadow enlarged. It is possible to make out the shape of small letters about ½-inch long cut out in the middle of a sheet of lead, if they are placed close to the eye. It makes very little difference whether the eyelid is open or shut. The front of the eyeball in my experiment was about 4 inches from the platinum radiating plate.

The condition for success is that the observer should be in the dark for some time—not less than ten minutes, and in some cases twenty minutes. A person who has recently been in full daylight appears to require a longer time in the dark before the sensitive condition is developed.

Mason College, July 1. GUY OLIVER HARRISON.

Distant Stars.

IN the interesting extract of Prof. Newcomb's address at the Flower Observatory, University of Pennsylvania, given in NATURE, p. 139, on the distance of the stars, he says:—

"Evidence is gradually accumulating which points to the probability that the successive orders of smaller and smaller stars, which our continually increasing telescopic power brings into view, are not situated at greater and greater distances, but that we actually see the boundary of the universe," &c.

It would be extremely interesting if some of the reasons for this theory were given; it seems so startling to imagine that after all we are practically the "hub of the universe," or very nearly so; and so opposed to the idea that what our most powerful telescopes can show, may possibly only be in proportion to the whole universe as one drop of water to the Atlantic Ocean.

ALBERT COLLISON.

Sound of Distant Firing.

I SEE a correspondent reports hearing the saluting at the Portsmouth Naval Review at Chelsea. It was distinctly audible here, loud enough to be heard at some distance further, though the wind was E.S.E., a fresh breeze, and therefore unfavourable for helping sound. Also there were no clouds—in sight, anyhow—which might aid in reflecting the sound-waves. The reports began a few minutes after 2 p.m., and continued at intervals up to nearly three o'clock, at which time I ceased listening for them. I make the air-line distance just sixty statute miles.

I may add that, when walking on Wimbledon Common, I frequently hear loud detonation, which I put down to Shoeburyness, as I do not know of any other place in that direction at which heavy firing takes place. The distance would be about fifty miles, but across London, which one would think might interfere with sound-transmission. C. MOSTYN.

Wimbledon, July 12.

Blackbird's Nest appropriated by a Wagtail.

THE double bird's nest I send you was found some time ago in a stack of hop-poles when they were taken down for use. The lower nest is clearly a blackbird's, and in it, below the lining, were two blackbird's eggs when found. The upper nest (or lining?) is, I am informed, that of a pied-wagtail, with four eggs, and also the egg of a cuckoo. It is suggested the blackbird was disturbed (by a cuckoo?), and a wagtail, assuming the nest, completed it in its own fashion, the cuckoo therein laying its egg. (The same cuckoo which had disturbed the blackbird?)

The double nest was found by Mr. Pattenden, a farmer here, and seen by his wife and son *in situ*. I have sent you a letter written by the son, and stating how the nest was found. I do not doubt the story is true. F. C. CONSTABLE.

Burwash, Sussex, July 7.

THE ETIOLOGY OF YELLOW FEVER.

YELLOW fever is an acute infectious disease, endemic in the West Indies, the shores of the Mexican Gulf, and in some parts on the West Coast of Africa, whence the disease has been repeatedly transported into other localities, causing here epidemic outbreaks. Like other infectious diseases, yellow fever is supposed to be caused by a specific living entity which, invading a predisposed person, multiplies there and causes the peculiar pathological changes in the gastro-intestinal tract and the liver, characterising yellow fever. Within recent years the supposed specific microbe has been discovered several times. Dr. Domingos Freire, of Brazil, and Dr. Carmona y Valle, of Mexico, have announced such discovery, but Dr. Sternberg, of Washington, who has himself studied the disease on behalf of the United States Government, has shown that none of these discoveries are a reality, and after a prolonged investigation, including the examination of a great many cases affected with, or dead from the disease, has arrived at the following conclusions, embodied in a lengthy report to his Government: that none of the different species of bacilli and cocci, present in the intestinal canal, in the blood, the liver and other tissues of persons affected with yellow fever, can have a claim to be considered as the specific microbe; that in a number of cases the examination, microscopic and cultural, of the blood and tissues yielded no bacteria recognisable either by the known methods of staining or culture; and he finally implied that the specific microbe of yellow fever is most probably not of the nature of a bacterium at all. After these very definite conclusions by Dr. Sternberg, it came rather as a surprise when, some months ago, the announcement was made that Dr. Sanarelli, Professor of Experimental Hygiene in Montevideo, formerly in the Pasteur Institute in Paris, had discovered the true cause of yellow fever in the form of a bacillus, *Bacillus icteroides*. This surprise is still further heightened by the statement in Dr. Sanarelli's lecture, that the *Bacillus icteroides* is demonstrable by the ordinary methods of staining and by culture in the ordinary well-known media. The morphological and cultural characters of the bacillus show it to belong to the group of coli-like bacilli; it is rarely demonstrable in a pure state in the blood or tissues, being generally associated with a more or less copious admixture of other microbes—*Bacillus coli communis*, *streptococci* and *staphylococci*; as a rule it is present only in small numbers in the capillary blood-vessels of the liver, spleen and kidney. It reflects great credit on the perseverance and sagacity of Dr. Sanarelli to have been able, notwithstanding all these difficulties, to select out the *Bacillus icteroides*, and to have by animal experiment been able to demonstrate, at least, as highly probable that the *Bacillus icteroides* is the true microbe of yellow fever. As mentioned just now, the distribution of the microbe in the affected person, its morphological and cultural characters do not in themselves offer strong *prima facie* evidence, and Dr. Sanarelli himself fully recognises this; but when we come to the experimental evidence which he furnishes, the evidence as to the *Bacillus icteroides* being the specific cause of yellow fever assumes considerable power.

In the first place, Sanarelli shows that dogs, goats, and horses are susceptible to infection both with the living bacilli as also and particularly with the highly poisonous toxin produced by the bacilli in broth culture; the symptoms and anatomical lesions hereby produced in these animals in the intestinal tract, the liver and the kidney, bear a striking resemblance to those of yellow fever in man. In the second place, Sanarelli furnishes proof that the toxin produced in broth culture—and separated from the bacillary growth by filtration through a Chamberland filter—when injected into healthy persons causes a prompt reaction in the form of severe disturbance, primarily of the intestinal tract, but also, further, of the general system closely resembling that in yellow fever. It is to be hoped, nay, it may be assumed as certain, that in continuing his investigations Dr. Sanarelli will ascertain the action of the blood of human beings, who have passed through, and recovered from the disease, on the *Bacillus icteroides*. This disease, as is well known, very rarely occurs twice in the same person, and it is therefore highly probable that, as is the case in other similar infectious diseases, the blood after a single attack possesses agglutinating action (*in vitro*), or germicidal action (*in corpore*), or both on the culture of the specific microbe. If on further investigation the blood serum, after an attack of yellow fever, should be found to show such positive actions on the *Bacillus icteroides*, a strong support will thereby be furnished as to this bacillus being the specific microbe. It will be the crowning of prolonged and laborious studies, if Sanarelli by experiments on immunisation of animals—the horse being evidently well fitted for such immunisation—did, as is highly probable that he will, obtain antitoxic serum by which yellow fever can be successfully combated both prophylactically and therapeutically.

E. KLEIN.

THE VARIABLE STAR η AQUILÆ.[1]

THIS essay contains a full discussion of all the available observations of a remarkable variable star, the fluctuation of whose light presents many features the explanation of which is still beset with much difficulty. Of the 12,000 recorded comparisons of the relative brightness of η Aquilæ and neighbouring stars, no less than 7147 are due to the indefatigable perseverance of Julius Schmidt, who for the last twenty years of his life (1859–1879) was director of the observatory at Athens. Taking advantage of the preponderance of Schmidt's records over those of all other observers, the author first investigated the variations of the star's light as shown by these alone, and then examined in how far the results thus obtained were confirmed by the labours of other observers. The discussion of Schmidt's observations was complicated by the circumstance that in the majority of cases he only used two comparison stars, β and ι Aquilæ, one of which there was great reason to believe was itself variable. From the 1700 occasions on which both stars were used, Dr. Lockyer found ι to vary 1·7 grades of Schmidt's scale with a period of about thirty-five years. Associated with this long-period change, the relative brightness of ι was shown to be subject to an annual variability of about one grade, which is clearly traced to the influence of the hour angle at which the stars were compared. This apparent annual variation is, therefore, identical with the "position error" noted by many observers of variable stars, and which has lately been investigated so thoroughly by Mr. Roberts, of Lovedale, South Africa. Schmidt's observations, freed from both the above variations as well as from the slight aberration error due to the changing position of the earth in its orbit, were all reduced to the meridian of Bonn. Owing to the general sparseness of the data, it was necessary to combine the observations of 100 periods, or about two years, into a group represented by a single curve. This was effected with the help of a provisional mean period and date of minimum for which Argelander's values of 7d. 4·234444h. and 1848, May 18d. 6·4333h. M.T. at Bonn were adopted, the date being that of epoch 400. To further facilitate the construction of the curve the mean

[1] "Resultate aus den Beobachtungen des Veränderlichen Sternes η Aquilæ." Inaugural Dissertation zur Erlangung der Doctorwürde, von William J. S. Lockyer. 5 plates, quarto, pp. 95. (Göttingen: 1897. London: Dulau and Co.)

brightness in each 6-hour interval of the period was set down for each group, together with the corresponding time and the number of observations. In this way the whole of the materials collected by Schmidt from 1844 to 1879, and thus covering eighteen groups of 100 periods each, are expressed in tabular form on p. 21 of Dr. Lockyer's dissertation. The numbers for each period were then plotted on millimetre paper; tentative and afterwards definite curves representing the fluctuations of the star's light were drawn through the points thus obtained. The resulting eighteen curves representing Schmidt's observations are reproduced one above the other on a small but distinct scale on Plate I., each curve being prolonged by about one-third of the period to bring out the form of the minimum. A study of these curves shows that Argelander's period cannot, at present, be improved on as a mean value. The *time* of Argelander's epoch 400 is, however, shown to be too early by an interval which the author fixes at 3·2655 hours. The curves also show conclusively that the epoch of maximum oscillates to and fro to the extent of five hours on either side with a period comprising 400 maxima. In the same way the minima are subject to an oscillation of about three hours in approximately 2400 periods. The combined effect of these variations causes the light-period to vary between 7d. 4h. 14m. 40s. and 7d. 4h. 13m. 28s. also in 2400 periods. Superposed on the main light curve are four subordinate undulations, of which more hereafter.

Much the same method was followed with regard to the observations of Argelander, Schönfeld, Heis, Plassmann, Oudemans, Pannekock, Auwers, Knopf, Sawyer and Schur; but with the further step of reducing the estimated grades to Argelander's scale. This reduction, carried out with scrupulous care by the method of least squares, brings out several interesting facts regarding the values which the grade, or unit of brightness, assumes in the case of the different observers, or for the same observer at different times. Here there is only space to mention the observations made by Knopf in Jena. Contrary to the general usage of comparing a variable with stars differing from it in brightness by at most five or six grades, Dr. Knopf often allowed himself a range of no less than nineteen grades. This new departure has most unexpectedly had no injurious effect on the accuracy of the observations, as is abundantly proved by the smallness of the residuals in the evaluation of the brightness of the comparison stars. From the materials collected by the observers just named, the author constructed nineteen further curves, which confirm in a high degree the results from Schmidt's observations alone. Dr. Lockyer also tests the accuracy of his conclusions by means of the long series of observations made by Wurm in the course of twenty-seven years, beginning with 1785. The detail, indeed, of these observations seems never to have been published, but the actual length of the period in accordance with Schmidt, for the epoch of Wurm's observations, differs but seven seconds from Wurm's value; and since the early observations also show decided indications of the oscillation of the time of maximum, it seems certain that the general character of the variability of η Aquilæ has not materially changed in the course of the last hundred years.

As regards the four secondary fluctuations, they are found to recur at intervals of forty-three hours, or one quarter of the main period, the first of these secondary maxima occurring fifteen hours after the chief minimum. The author is the first to have clearly brought out this feature, and he explains it by assuming, in accordance with his father's hypothesis, that the system of η Aquilæ consists of three meteoric swarms, of which the two lesser revolve about the greater in periods of 1d. 19h.+ and 7d. 4h.+ respectively (see "Meteoritic Hypothesis," *passim*, but particularly pp. 475–6). The irregularities in these fluctuations are set down to the perturbations necessarily occurring in such a system, but their investigation did not come within the scope of the essay before us. Figs. 1 and 2 of the dissertation show the proportions of the assumed orbits, together with the form of the light curve resulting from the combination of the two elementary curves. In conclusion, I must express my admiration of the skill and untiring perseverance which Dr. Lockyer has shown in dealing with a large mass of somewhat intractable material. Wherever possible the deductions were made from the original manuscripts, concerning which interesting particulars are given on pp. 19 and 20, where we learn that Schmidt's original notes are preserved at Potsdam, while those of Heis have wandered across the Atlantic to the observatory of Georgetown College.

R. Copeland.

BRITISH ASSOCIATION TORONTO MEETING.

III. Local Arrangements.

The two leading Hydraulic Companies of Niagara Falls are making special arrangements for the reception of the members of the British Association.

The Carborundum Company of Niagara Falls has extended an invitation to the members of the Association to visit and inspect the Company's works on Saturday, August 21. The manufacture of carborundum by this Company has been fully described in Nature for May 13 (p. 42).

The Atlantic Cable Companies have generously arranged that members from Great Britain may send two free cable messages from Toronto, and they will then be entitled to two free replies. Each message and reply are not to contain more than ten words each, and they are to be forwarded by agents recognised by the Cable Companies. The agents in Great Britain will, in all probability, be Messrs. Cook and Son, and in Toronto the Honorary Local Secretaries; but the arrangements in regard to this are not complete, and a fuller announcement will be made later. It is to be noted that the transmission of the messages within Great Britain to and from the head office of Cook and Son will be charged for as ordinary telegraphic messages. The arrangements in this respect are the same as those made in 1884.

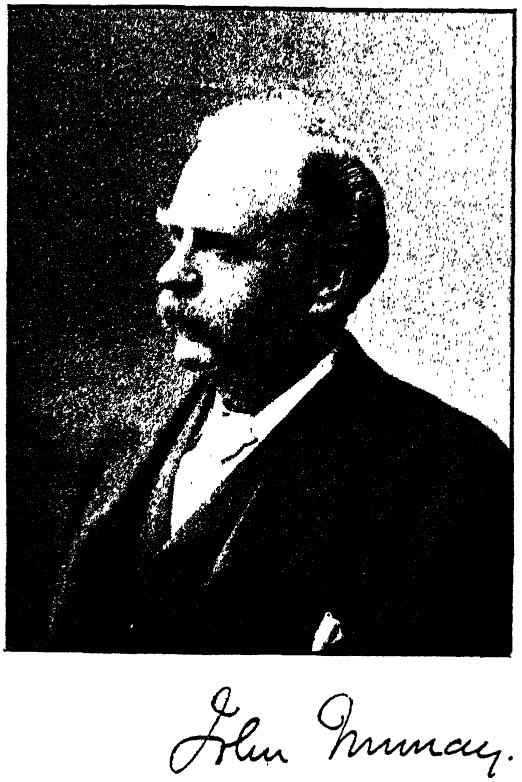
In order to avoid delay in the Customs examination of the members' luggage, the Hon. Mr. Paterson, the Minister of Customs, has given special instructions to the Customs officers at Quebec, Montreal and Niagara to facilitate in every way the examination. A larger number of examining officers will be on duty at Quebec, and one will accompany each steamer from Quebec to Montreal to make the examination of the luggage during the passage. As a result of this arrangement, all delay at Quebec and Montreal will be avoided. The Minister of Customs has also arranged that all scientific apparatus or material for use during the meeting of the Association shall be admitted free of duty if forwarded to me at Toronto, and marked, "For British Association."

It is expected that there will be in attendance at Toronto more than twenty continental men of science of a representative character. Amongst those who have intimated their intention to be present are Prof. Charles Richet, Prof. Yves Delage, both of Paris; Prof. Meslans, University of Nancy; Prof. Gilson, of Louvain; Dr. van Rijckevorsel, of Amsterdam; Dr. Pauli, of Frankfort; Prof. Ladenburg, of Breslau; Prof. Runge, of Hanover; Prof. Brauner, of Prag; Prof. Penck, of Vienna; M. Letourneau, of Paris; M. Gobert, of Brussels; and Prof. P. Magnus, of Berlin.

A. B. Macallum.

THE "CHALLENGER" ALBUM.

AT the Ipswich meeting of the British Association, a couple of years ago, a movement was started amongst the zoologists present to congratulate Dr. John Murray, and offer him some memorial of their appreciation of his services to science, on the completion of his editorial work in connection with the fifty volumes of the *Challenger* Reports. A Committee was formed, with Mr. W. E. Hoyle as Secretary, and the offering eventually took the appropriate form of a handsome album containing the portraits and signatures of the contributors to the *Challenger* Series, with an artistic cover and illustrated dedication designed by Mr. Walter Crane. The presentation was made to Dr. Murray at a meeting held in London on November 30, and the happy thought then occurred to Mr. Hoyle to have the volume, cover, dedication and photographs reproduced, so that all contributors, and some others, might have, if they desired, a



copy of this interesting memorial of the completion of the *Challenger* work. The result is now before us in the form of a thin quarto volume, bound in dark green cloth like the *Challenger* Series, and containing some twenty sheets of portraits, along with reproductions of all Mr. Crane's quaint drawings, and an explanatory introduction drawn up by Mr. Hoyle. Messrs. Dulau and Co. have issued an edition of two hundred copies at 12*s*. 6*d*. each. Most of these are being secured by the contributors, but some copies can be obtained by libraries and individuals who desire to add this supplemental volume to their *Challenger* Series. Some of the original photographs were very good, others were poor, and naturally some of the reproductions are better than others; but all the portraits must be of considerable interest to those who possess, and to those who read the *Challenger* monographs. The volume is similar in size and style to the well-known Reports, and containing as it does portraits of all the eighty-eight contributors to the *Challenger* work, the pity is that there are not enough copies to go round all the libraries that contain the *Challenger* Series. We are enabled to show here the portrait of Dr. Murray himself.

NOTES.

THE Sydney expedition to Funafuti, to make borings in the coral, projected and led by Prof. David, started on June 2, going by steamer to Fiji, and thence by sailing vessel to Funafuti. This expedition has been made possible by the liberality of the Mining Department of the Government of New South Wales, which has supplied all the boring plant free of cost, and by the munificent gift from Miss Walker, of Sydney, of 500*l*., and from the Hon. Ralph Abercrombie of 100*l*. towards the expenses of the expedition.

PROF. SOUILLARD, of Lille, has been elected a corresponding member of the Paris Academy of Sciences.

THE following are the names of the presidents of the several sections of the Australasian Association, the next session of which will be opened on January 6, 1898, under the presidency of Prof. Liversidge, the president-elect:—Section A—Astronomy, Mathematics and Physics, R. L. J. Ellery. Section B—Chemistry, T. C. Cloud. Section C—Geology and Mineralogy, Captain F. W. Hutton. Section D—Biology, Prof. T. J. Parker. Section E—Geography (president to be appointed). Section F—Ethnology and Anthropology, A. W. Howitt. Section G—Economic Science and Agriculture, R. M. Johnson. Section H—Engineering and Architecture, H. C. Stanley. Section I—Sanitary Science and Hygiene, Hon. Allan Campbell. Section J—Mental Science and Education, John Shirley.

THE third annual meeting of the Botanical Society of America will be held in Toronto on August 17 and 18, under the presidency of Dr. J. M. Coulter. The address of the retiring President, Dr. C. E. Bessey, will be given on the evening of the opening day.

THE summer meeting of the Institution of Mechanical Engineers will open at Birmingham on Tuesday, July 27. On the morning of that day there will be a reception by the Lord Mayor in the Examination Hall of the Municipal Technical School. The papers to be read and discussed deal with "Some Points of Cycle Construction," by Mr. F. J. Osmond; "The Birmingham Corporation Waterworks," by Mr. Henry Davey; "High Speed Self-lubricating Steam Engines," by Mr. Alfred Morcom; "Mechanical Features of Electric Traction," by Mr. Philip Dawson; and "Diagram Accounts for Engineering Work," by Mr. John Jameson. A large number of works in Birmingham, Wolverhampton, Oldbury, Tipton, Walsall, and Coventry will be thrown open for the inspection of members. On Wednesday the excursions will be to Wolverhampton district, on Thursday to Stratford-on-Avon and Walsall, and on Friday to Coventry, Warwick, and Rugby.

THE Paris correspondent of the *Times* reports that at the meeting of the Institute of France on July 7, the chief business of the sitting was the consideration of the bequest made to the Institute by the late Duc d'Aumale of his estate of Chantilly, and the discussion as to whether the conservators of the château and grounds should be appointed for life or for three years only. By 58 votes to 53 the Institute decided that the appointment should be for three years, and M. Mézières, of the French Academy, M. Gruyer, of the Academy of Fine Arts, and M. Léopold Delisle, of the Academy of Inscriptions and Belles Lettres, were almost unanimously chosen as conservators for the next three years. The conservators of the new "Condé

Museum" are to receive an annual stipend of 3000f. and to be lodged at Chantilly. The financial administration of the estate will not, however, devolve upon them, but upon three other members of the Institute to be subsequently appointed. Later information has been received saying that M. Limbourg has been appointed Administrator-General of Chantilly.

WE regret to notice the death of Prof. W. Marmé, Director of the Pharmacological Institute of Göttingen; Dr. Giuseppe Fissore, formerly Professor of Pathology in the University of Turin; Dr. E. Legros, Professor of Physiology in the new University of Brussels; and Dr. Maréchal, formerly Professor in the Naval Medical School of Brest. The last-named died of septic poisoning.

MR. R. D. OLDHAM, the Acting Director of the Geological Survey of India, has sent to a correspondent a letter on the recent earthquake in Calcutta, from which we have been permitted to make the following extracts:—"I was at Naini Tal at the time, and as soon as I knew how bad it was, came down here [Calcutta] to make arrangements for a thorough investigation of it. At present it is not possible to say more than that it is the biggest and most severe of which there is any record in India, and that its investigation will be attended by considerable difficulty and inconvenience, not to say hardships, to the men employed, owing to the rainy season having commenced immediately after the earthquake. I have had orders from Government to prepare a full and detailed scientific report in the Geological Survey Department; have issued circulars to all station masters, telegraph officers, and other people likely to be able to give information, and have despatched every available man to investigate the damage done at all accessible places. Some that would have been worth visiting are, unfortunately, inaccessible at this season of the year."

IN addition to the foregoing communication we have received a lengthy letter on the subject, and a photograph, from Mr. T. D. La Touche; and these we hope to publish in a subsequent issue.

A DINNER was held on the 7th inst., under the presidency of the Duke of Cambridge, to commemorate the twenty-first anniversary of the formation of the Sanitary Institute. Speeches were delivered by Lord Kelvin, Sir Douglas Galton, Prof. Corfield, and others.

The American Naturalist notes that Dr. W. H. Evans, of Washington, D.C,, has gone to Alaska for several months to investigate the agricultural resources and possibilities of that portion of the territory lying south of the Aleutian peninsula. He will report to Congress as to the advisability of establishing experiment stations there. Dr. Sheldon Jackson is to collect similar information regarding the Yukon Basin.—Prof. Nelson, the University of Wyoming botanist, will make an excursion into the Red Sea Desert. This tract of land has, so far, never received a botanical investigation, and the Professor has planned to make three other trips into the desert during the summer. He expects to obtain many rare botanical specimens.—Prof. Bruner, of the University of Nebraska, has sailed for Buenos Ayres, where he will spend a year investigating the injurious locusts which have, of late, increased enormously in three of the eastern provinces of the Argentine Republic.

WE learn from the *Journal of Botany* that Mr. George Murray and Mr. V. H. Blackman have sailed for the West Indies, in order to work at the plant-plankton of the Atlantic, especially the forms found remote from coastal waters, such as the coccospheres and rhabdospheres. Their method of capture is by pumping sea-water through very fine silk bags, thus attaining practically the same result as by the tow-net, and without stopping the ship.

ACCORDING to *Science*, Major Powell is at present on the coast of Maine, engaged in research concerning shell mounds, in the interest of the Bureau of American Ethnology.

A MEETING was recently held in Glasgow, on the initiative of the Lord Provost, the Principal of the University, and the President of the Faculty of Physicians and Surgeons, to further the proposal to establish a memorial to William and John Hunter, and an executive committee was appointed to collect subscriptions; it is hoped that from 3000*l*. to 4000*l* may be raised.

THE Berlin Town Council, on the motion of Prof. Virchow, has decided to appoint a municipal "hydrologist," for the constant examination and hygienic supervision of the different Berlin waterworks. In connection with this appointment, the creation of a municipal board of health for the city of Berlin is being much discussed. If such were established, the municipal hospitals, orphanages, and asylums would be placed under its control, and also the municipal schools.

THE Park Board of New York City has adopted the plans for the buildings of the new Botanical Gardens in Bronx Park, as modified by the directors in accordance with the advice of the committee appointed to consider the question.

THE German *Imperial Gazette* of a recent date contains the regulations issued by the Government for the sale of Prof. Koch's new tuberculin, under which name the new specific will be sold by chemists in phials containing one millilitre at marks 8.50, and in phials containing five millilitres at marks 42.50. The tuberculin will only be given to certificated medical men, or to those provided with an authorisation from such.

THE July part of the *Journal of Anatomy and Physiology* announces that in consequence of the death of Sir George Murray Humphry, it has been considered advisable to reorganise the editorial staff. With the October part the *Journal* will, as regards anatomy, be conducted by Profs. Sir W. Turner, MacAlister, Cunningham and Thane; and the physiological department will, as heretofore, be in the hands of Prof. M'Kendrick.

IN our issue for June 24 we briefly described the run of the *Turbinia* from the Tyne to the Solent. We understand that during the three weeks the *Turbinia* was in the Solent she made frequent runs of many miles at a time, at speeds of from 30 to 35 knots, and that her performances were witnessed by many leading authorities in naval matters, as well as the mercantile marine. On Tuesday, June 29, with a distinguished company on board, she was run up to nearly full power, and maintained the unprecedented speed of 35 knots, or over 40 miles per hour, for the length of the line of battle-ships, or about 5 miles. During this run there was an absence of strain, and from this fact it seems that the limit of speed in this little vessel has not yet been reached, and that after further improvements, at present in progress (having returned to the Tyne last week), she will be capable of not only maintaining her position as much the fastest vessel afloat, but will be able to give many knots to any competitor engined with reciprocating engines. We purpose, in a subsequent issue, to give a further account of the compound turbine engines which, by the most direct and economical conversion of the power of the steam into effective horse-power in engines of unprecedently small weight, enable the *Turbinia* to achieve without stress or vibration such remarkable results.

THE Pilot Chart of the North Atlantic Ocean for July, issued by the American Hydrographic Office, contains a supplementary chart showing the tracks of floating bottles which have been returned to that office during a year ending June 1 last. Of

the bottles recovered, eighty-one were thrown overboard in the North Atlantic, and these are the only ones dealt with upon the chart in question. Taken collectively, the courses followed by the bottles elucidate the main principles of oceanic circulation, and show the close agreement that exists between the motion of the surface water and the direction of the prevailing winds. Dividing the list into groups, according to latitude, and dealing only with those bottles whose drifts exceed 300 miles, we have the following average velocities of the daily drift:—North of 50°, 5·3 miles; between 40° and 50°, 5·3 miles; between 20° and 40°, 5 miles; between 0° and 20°, 9·8 miles. A noteworthy drift shown on the chart, is that of a bottle thrown overboard in lat. 2° 9′ S., long. 30° 25′ W., and picked up on the African coast, at the mouth of the Bathurst River. This bottle, set adrift in the strong south equatorial current, must have been transferred to the Guinea current, and carried by it to the exceptionally northern position at which it was recovered.

THE Director of the National Observatory at Athens (M. Eginitis), has made an important contribution to the meteorology of Southern Europe by the publication of a careful discussion of the observations at Athens during the present century, and now continued at the Observatory. Although there are several interruptions in the continuity of the earlier observations, they have been carried on regularly during the last thirty-seven years. The discussion, which extends to 220 large quarto pages, contains an exhaustive account of the climate, each element being separately treated, and, in addition to the instrumental observations, notice is taken of all information obtainable from the most ancient periods. The absolute extremes of temperature vary from 105·3° to 19·6°, giving a range of 85·7°. Rain falls, on an average, during ninety-eight days in the year, the normal annual amount being 16 inches. Athens enjoys a large amount of sunshine, the values recorded by a Campbell instrument in 1894 amounted to 2527 hours; at Eastbourne in the same year the amount registered by a similar instrument was 1669 hours. In some years the sun shines incessantly from morning till evening, for a month at a time.

THAT birds play an important part in relation to agriculture has long been known to ornithologists; but farmers have a tendency to dwell upon the harm they do, rather than the benefits received. A better feeling is, however, being cultivated by means of the publications of the Society for the Protection of Birds, by County Councils, and by a host of books on birds; so that the hope may be cherished that agriculturists will soon be able to discriminate between their feathered friends and foes. In the United States, serviceable knowledge of this character is communicated to all who are concerned with it. For instance, in the *Farmers' Bulletin* (No. 54), which has just been issued by the U.S. Department of Agriculture, Mr. F. E. L. Beal describes "Some Common Birds in their Relation to Agriculture." The *Bulletin* contains short accounts of the results of food studies of about thirty grain and insect eating birds belonging to the different families. It is pointed out that the value of birds in controlling insect pests should be more generally recognised; for while it may be an easy matter to exterminate the birds in an orchard or cornfield, it is an extremely difficult one to control the insect pests. How very valuable birds are, is illustrated by the fact that during the recent plague of Rocky Mountain locusts in the Western States, it was found that locusts were eaten by nearly every bird in the region, and that they formed almost the entire food of a large majority of this species. In winter sparrows are active weed destroyers, weed seed forming an important item of the winter food of many of these birds.

THE uncertainty which attaches to the specific-heat-ratio of gases as a means of distinguishing between monatomic and polyatomic molecules renders it of great interest to investigate other properties dependent on the molecular volume or cross-section. In the *Proceedings* of the American Academy of Arts and Sciences, xxxii. 11, Messrs. A. A. Noyes and H. M. Goodwin describe a new determination of the viscosity of mercury vapour and its comparison with those of hydrogen and carbon dioxide, the method used consisting in measuring the flux through a capillary tube under constant difference of pressure. By the application of O. E. Meyer's formula, the authors deduce that the cross-section of the mercury molecule or of its sphere of action is nearly the same as that of the carbon-dioxide molecule, and about two and a half times as large as that of the hydrogen molecule. Whether the authors are justified in their conclusion, "that atoms and molecules are of the same order of magnitude," depends on how far the value of the ratio of the specific heats in mercury is admitted to be indicative, on the kinetic theory, of the monatomic nature of that gas.

A NOTE has been communicated to the *Atti dei Lincei* by Dr. Emilio Oddone, on an apparatus for determining the thermal conductivity of substances which are bad conductors. The apparatus is based on the model of one constructed and described by Dr. Venske, of Göttingen, in 1891, and the author describes a determination made by it for glass. It is proposed to apply the method to the conductivity of rocks, and we hope that the investigations will throw fresh light on the past history of the earth.

IN a very suggestive, privately published, essay entitled "Demeter und Baubo, Versuch einer Theorie der Entstehung unsres Ackerbaus," E. Hahn puts forward a number of new views, and combats many old ones. He believes that man was primitively an omnivorous "collector," later he severally diverged into a hunter, a fisher or a planter, or in certain districts into a herder; but he denies the evolutionary series of hunter, herder and agriculturist. He argues that the first cultivated plant was millet, and he draws a sharp distinction between hoe-culture and the cultivation of cereals with the use of the plough. He believes barley was the earliest cereal, and wheat the latest. There is no necessary connection between our method of tillage with the plough (with the keeping of domestic animals), and the use of milk. Cattle were first domesticated as draught animals and to draw the plough, and it was only long afterwards that they were trained to yield milk for human food. The author is greatly impressed with the effect of religion on the progress of early culture; for example, he holds that the waggon was originally employed for the transport of effigies of the goddess of fertility, probably the moon, and that later it became a secular vehicle. He does not believe that wheels were evolved from rollers, but that they were derived from spindle-whorls, four of which were attached to a board, and so arose the diminutive and primitive conveyance of the goddess. The author invites criticism, and would be glad of references to researches bearing on his subject; these should be addressed to him, care of Max Schmidt, bookseller, Lübeck.

HERR F. R. FRIIS has just completed and published the correspondence between Tycho Brahe and Oligerus Rosenkrantz during the years 1596 and 1601. This book, which is entitled "Epistolæ quas per annos a 1596 ad 1601 Tycho Brahe et Oligerus Rosenkrantzius inter se dederunt," contains in its 80 pages twenty-four letters, most of which were written by Tycho Brahe *to* Rosenkrantz. In the appendix are given ten other interesting communications, written about the same time. The compiler of this collection is to be congratulated on the important service he is rendering history by this collection, which is a further addition to letters already published. The first publication was entitled "Tychonis Brahei et ad eum doctorum virorum Epistolæ ab anno 1568 ad annum 1587," and

was accompanied "cum effigie Tychonis Brahei et exemplo ipsius manus." We may mention that only a small number has been printed, and those wishing to acquire copies can do so from the following address:—F. R. Friis, Copenhague, Cart Adelersgade 7.

THE report on the operations of the Department of Land Records and Agriculture, Madras Presidency, for the official year 1895-96, has just reached us, and is full of interest. The department, during the period under survey, appears to have been most active in the performance of its duties, and good work was carried on, or attempted under, in many instances, great disadvantages. The unfavourable character of the weather caused a failure in many of the planting experiments. Courses of lectures were delivered on the subjects of agricultural chemistry and veterinary science, and experiments were made with various kinds of ploughs in Kurnool district. Inquiries were made "as to whether any animal or vegetable parasites have been anywhere observed, or can be found feeding upon the prickly-pear in such a manner as to warrant a hope that it might be used as an agency for destroying the said plant," and the opinion arrived at, from the reports received, was that there are no parasites known in the Presidency which can be depended upon to destroy prickly-pear growth.

THE alleged reflexion of kathodic and Röntgen rays have been made the subject of two independent but closely-allied investigations by Prof. A. Battelli (*Nuovo Cimento*, v. 4) and M. P. Villard (*Bull. Société Française de Physique*, 95). Prof. Battelli's conclusions are as follows: (1) It cannot be asserted that kathodic rays are reflected according to the regular law; (2) rays coming from the speculum of a focus-tube have the same properties as direct kathodic rays; (3) the same properties are possessed by rays coming from the anterior face of a very thin lamina, on whose posterior face kathodic rays impinge; (4) a pencil of such rays seems to be constituted of different kinds of rays which, when they fall on a thin body, appear to traverse it in somewhat the same manner that they would traverse a filter which allowed some rays to pass through more freely than others. M. Villard finds that kathodic rays that have fallen on a thin metallic lamina, emerge in the form of a diffused pencil, whose general direction is normal to the lamina, but the phenomenon appears to be a kind of refraction. Reflexion is more easily obtained, and the phenomenon can be photographed; the reflected rays possess all the properties of kathodic rays, and are strongly deflected by the repulsive action of the kathode. Experiments show that this reflexion, though evidently anomalous, is perfectly definite.

DR. ITALO BOSI contributes to the *Nuovo Cimento*, 4, v. a series of observations on the electric resistance of solutions of salts in motion, which have an important bearing on Hittorff's and Arrhenius' theories of electrolysis. Dr. Bosi finds that in solutions where the effect of electrolysis is to produce greater concentration at the positive pole, the resistance increases when the liquid is moving in the opposite direction to the current, and decreases when it is moving in the same direction; but the increase in the first case is greater than the decrease in the second. Where the concentration is greater at the negative pole the effect is reversed; the increase of resistance, however, still exceeds the decrease. Finally, when electrolysis produces no difference of concentration at the two electrodes, the resistance is unaffected by the motion of the liquid. These conclusions do not entirely accord with the hypotheses either of Hittorff or of Arrhenius. An investigation somewhat allied to the present had previously been made by Edlund, but this was rather qualitative than quantitative in character, and, moreover, the fluids used by Edlund (town water, alcohol and water, and others) left some doubt as to the nature of the dissolved salts contained in them.

THE *American Naturalist* for June contains an account, by Mr. G. C. Whipple, of the biological laboratory instituted by the Boston Water Works for the examination of the purity of the water supplied to that city. The object of the laboratory work is to ascertain and keep a record of the condition of the water in all parts of the supply at the same time. The microscopical work consists chiefly in the quantitative determination of the various microscopic organisms, except bacteria, in each sample of water, by the Sedgwick-Rafter method. In addition to this, the number of bacteria is determined in the water of all the reservoirs, aqueducts, and service-pipes, and a careful watch is kept for those of a pathogenous character. It is stated that the work done in this and in other similar biological laboratories in Massachusetts (there is a separate one for the city of Lynn) has been of great value, both from a purely scientific and from a sanitary point of view, and that by these investigations the supply of inferior water has several times been prevented.

IN "Minnesota Botanical Studies" (*Bulletin* No. 9, Parts x. and xi.), published by the Geological and Natural History Survey of Minnesota, are several papers of more than local interest. Mr. J. M. Holzinger calls attention to some mosses found by him at high altitudes. On Pike's Peak, Colorado, between altitudes of 12,502 feet and the top of the peak (14,147 feet), he collected thirty species of mosses which deserve attention. Mr. R. N. Day contributes a paper on the relative value of various forces operative in the production of the positions of dorsiventral leaves. He concludes that light cannot induce epinasty or hyponasty, and adds: "This is in direct support of the position taken by Vines, and the results upon which it is based demonstrate that the photo-epinasty of Detmer does not exist as such." Mr. A. A. Heller gives a valuable description of the ferns and flowering plants of the Hawaiian Islands; and the phenomena of symbiosis is the subject of a paper by Mr. Albert Schneider. Mr. Conway MacMillan, State Botanist of Minnesota, discusses his observations of the distribution of plants along the shores of the Lake of the Woods, the purpose of his paper being to point out the dependence of plant formations over such an area as the shores of the lake upon topographic and environmental conditions. It is shown how each formation may be explained briefly as connected with a certain *mélange* of outward conditions, and an effort is made to analyse these conditions both by themselves and as connected with the growth of vegetation.

THE first part of an "Essai sur les éléments de la mécanique des particules," by M. H. Majlert, has been received from MM. Gauthier-Villars et Fils, Paris. The object of the work is to bring forward some new geometrical views on problems of hydrodynamics. In the present part, entitled "Statique particulaire," the author deals with general principles referring to matter and energy, atoms and molecules, states of aggregation of simple bodies, chemical combinations, and co-related subjects. He reserves for a second part, to be published under the subtitle "Dynamique particulaire," the results of his special studies on energy and its manifestations; and we reserve our review of the work until that part appears.

THE fourth number of *Archives of Skiagraphy*, edited by Mr. Sydney Rowland, has just been published. Among the subjects and objects illustrated upon the six collotype plates are the dislocation of an elbow, fracture of radius and ulna, the lobster, edible crab, hermit crab, and five of Dr. Macintyre's Röntgen photographs of a frog's leg in movement.

SEVERAL articles on subjects of scientific interest appear in the July magazines. Mrs. Percy Frankland gives in *Longman's Magazine* an outline of the rise and development of bacteriology during the past sixty years; and to *Good Words* she contributes a sketch of the career of the great leader of bacteriological

science, Pasteur. The Zoological Gardens at Amsterdam are described in *Macmillan's Magazine* by Mr. C. J. Cornish; and Mr. H. W. Seton-Karr narrates in the *Century* his hunting experiences in Africa and India, referring incidentally to his discovery of palæolithic flint implements in Somaliland. An interesting account of the discovery of the American continent by the Cabots, illustrated from original documents, autograph letters and ancient maps, is contributed to *Scribner's Magazine* by the Marquis of Dufferin.

THE Department of Agriculture, Brisbane, Queensland, has recently issued the second edition of "A Companion for the Queensland Student of Plant Life, and Botany Abridged," by Mr. F. M. Bailey, the Colonial Botanist. Many of the notes are given with a view to assist school teachers, and particularly those residing in the country districts, to some of the more prominent distinctive characteristics of common plants. We notice that copies of the pamphlet can be obtained free by persons interested, on application to the Under-Secretary for Agriculture, Brisbane.—A translation, by C. S. Fox, of the official "Guide to the Royal Collections of Dresden," comes to us from Albanus, of Dresden. In it will be found very full information as to the collections housed in the Museum (Zwinger), the Royal Palace, the Johanneum Museum, the Albertinum, and the Japanese Palace. It remains to be said that the Guide is very well got up.—The third report of the Commissioners of the Whitechapel Public Library and Museum has reached us, and contains much interesting matter. Science is not overlooked in Whitechapel, as the list of sixteen lectures by well-known men of science shows. The library contains, in its lending branch, 541 books dealing with natural science, and in works relating to voyages and travels 614 books. In the reference department natural science is represented by 444 works, and voyages and travels by 89. We are sorry to see that there was a falling-off in the number of readers of books dealing with the subjects mentioned, as compared with the numbers given in the preceding report.

AMONG official American publications relating to botanical and agricultural science recently received, are the following:—Twentieth Annual Report of the Connecticut Agricultural Experiment Station for 1896, chiefly devoted to the properties and analysis of fertilising manures; Studies on American Grasses, being Bulletin No. 8 of the U.S. Department of Agriculture, Division of Agrostology (New or little-known Grasses, by F. Lawson-Scribner; Leaf-structure of *Jouvea* and of *Eragrostis obtusiflora*, by Miss E. L. Ogden); Bulletins Nos. 141–144 of the Michigan State Agricultural College Experiment Station (Forage crops and Wheat; Small fruit trials at the College; Fruit tests at South Haven; Vegetables, old and new).

THE additions to the Zoological Society's Gardens during the past week include a Syrian Bear (*Ursus syriacus*, ♀) from the hills north of Bagdad, presented by Mr. B. T. Ffinch; a Ring-tailed Coati (*Nasua rufa*) from South America, presented by Mr. J. B. Gowing; an Osprey (*Pandion haliætus*) from Aberdeenshire, presented by Major-General Russell, M.P.; a Cayman-Island Amazon (*Chrysotis caymanensis*) from the Cayman Islands, presented by Mr. C. Home Sinclair; a Blue-fronted Amazon (*Chrysotis æstiva*) from South America, presented by Mrs. Reynell; a Shag (*Phalacrocorax graculus*) British, presented by Mr. Edward Step; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Miss Amy Meyer; a European Tree Frog (*Hyla aborea*) from Southern Europe, presented by Mrs. Nicolas Wood; a Bonnet Monkey (albino) (*Macacus sinicus*, ♂) from India, a Rock-hopper Penguin (*Eudyptes chrysocome*) from the Antipodes Islands, a Thick-billed Penguin (*Eudyptes pachyrhynchus*) from the Stewart Islands, a Graceful Ground Dove (*Geopelia cuneata*), two Ganga Cockatoos (*Callocephalon galeatum*) from Australia, deposited; a Dwarf Finch (*Spermestes nana*) from Madagascar, two Barred-shouldered Doves (*Geopelia humeralis*) from Australia, two Chinese Turtle Doves (*Turtur chinensis*) from India, purchased; an English Wild Bull (*Bos taurus*), two Common Blue-Birds (*Sialia wilsoni*), four White-backed Pigeons (*Columba leuconota*), two Triangular-spotted Pigeons (*Columba guinea*), a Spotted Pigeon (*Columba maculosa*), a Crested Pigeon (*Ocyphaps lophotes*), an Auriculated Dove (*Zenaida auriculata*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

JUPITER'S SATELLITES.—In a previous note we referred to the period of rotation of the third satellite of Jupiter as determined by recent observations made by Mr. Douglass at the Lowell Observatory. In the current number of the *Astronomischen Nachrichten* (No. 3432) he communicates a more detailed description of the observations, together with reproductions of the surface markings, which led him to the determination of the length of the period of rotation. Attempts were at first made to discover signs of surface movement within three to five hours of continuous observation. None, however, could be detected, so that the 24-hour period had to be discarded as untenable. A large series of sketches showed that the satellite's period was nearly the same as its period of revolution, namely, 7d. 5·1h. ± 1·2h. The surface markings seem to take the form of lines, their maximum width being estimated at less than 0″·1, or 200 miles. The fourth satellite was also observed minutely, and on its surface were seen markings which are described as similar to those found on the third. Its period of rotation was also noted as being probably nearly equal to its period of revolution round its primary. Prof. W. H. Pickering's discovery of the variability in the elongation of the first satellite seems to be confirmed by Mr. Douglass, who found this satellite at the time of observation "most remarkably elongated."

THE CONSTANT OF ABERRATION.—Mr. C. L. Doolittle has recently concluded a discussion of several observations with the object of determining the value of the constant of aberration (*Astr. Journal*, No. 406). The series of observations used possessed some special advantages for such an investigation, since the stars were distributed very uniformly throughout the twenty-four hours of right ascension, and each group was observed both morning and evening at approximately the same interval before and after midnight. In all, 107 pairs of stars were used, the series extending from 1892 October 10 to 1893 December 27: these included 1744 determinations before, and 1052 determinations after midnight. The final value obtained, namely,

$$20''\cdot55 \pm 0\cdot01$$

seems rather high when compared with those obtained by other investigators. The following brief table brings together a few of the results previously determined.

CATALOGUE OF 480 STARS FOR ZONE OBSERVATIONS BETWEEN −20° AND −80°.—Ten years ago Prof. Auwers published a list in the *Monthly Notices* of 480 stars to serve as standards for zone observations. It was then suggested that these stars should be systematically observed at those observatories situated in southern latitudes. Sufficient material has, however, been obtained to enable Prof. Auwers to publish in the current number of the *Astronomischen Nachrichten* (No. 3431–32) a complete catalogue of the positions of these 480 stars, together with a selection of nineteen other southern fundamental stars. Prof. Auwers mentions, however, that we must not treat the

places of all these stars as if they were as accurately determined as fundamental stars should be, because there was not in some cases sufficient material for the determinations of accurate proper motions. It is suggested that after an interval of fifteen to twenty years these stars should be again systematically observed and computed afresh. The catalogue, which is arranged for the epoch 1900, further contains the values of Bessel's constants computed for that year. There is also added the places of twenty-four stars, lying near the south pole, which have been chosen by Dr. Gill, and observed at the Cape Observatory.

LATITUDE OBSERVATIONS AT THE U.S. NAVAL OBSERVATORY, WASHINGTON.—Prof. W. Harkness describes the results of a determination of the latitude, and its observed variation, of the Washington Observatory in the *Astronomical Journal* (No. 404). The method employed involved the use of two instruments, namely, the transit instrument, of 77 inches focal length and 4·86 inches aperture in the prime vertical, and the meridian instrument of 30 inches focal length and 2·55 inches aperture; the latter could be used either as a transit instrument or as a zenith-telescope. The plan of work adopted was to observe α Lyræ at every possible culmination, both night and day, throughout the year, and also to observe four other stars near the times of their maximum aberration, in order to eliminate the latter constant from the latitude variation. The final result of the investigation is given in a table showing the observed values of the variation of the latitude.

APPEARANCE OF D'ARREST'S COMET.—A communication from America informs us that Prof. Holden telegraphs that D'Arrest's comet was observed by Perrine June 28·9764 Greenwich mean time. Apparent R.A. 30° 21′ 9″. Apparent polar distance 83° 46′ 29″. The ephemeris, which was given in *Ast. Nachr.*, No. 3405, requires the correction, according to Prof. Kreuz, of −3m. 58s. in R.A. and −4′·4 in declination.

SPECIES OR SUBSPECIES?

OF late attention has frequently been called in scientific journals to that rapid multiplication of nominal species of mammals which forms one of the most striking features of the systematic zoology of the last few years. To take an extreme instance: In eastern Europe and northern Asia there exists a pretty little rodent allied to the squirrels, and forming the single Old World representative of the genus *Tamias*. Until quite recently this creature was supposed to be common to North America, and was generally known as the Asiatic Chipmunk (*T. asiaticus*); and it is not many years ago that a well-known American zoologist fully recognised the specific identity of the eastern and western forms. Soon afterwards, that very same writer not only separated the American from the Asiatic race, but considered that the former constituted more than a score of distinct species! To take another example. The coyoté, or prairie wolf, has been very generally recognised as constituting a well-marked species distinguished from the ordinary wolf, not only by its inferior size, but by differences of colour and pelage. During the present year Dr. C. H. Merriam, the well-known Government zoologist of the United States, has, however, thought proper to split up the coyoté into a number of what he regards as distinct species. And it may be added that he has done the same for the brown and grizzly bears of his own continent, and also for those of north-eastern Asia.

It is, perhaps, needless to say that this species multiplication is a direct consequence of the increased attention which has been given of late years to the collection and description of mammals; and that, so far as the actual work itself is concerned, we have nothing but praise to bestow on the workers. Every one will admit that we ought to know as much as possible about all animals, and that if an American bear, wolf, or stoat can be distinguished from its cousin of the Old World, it is right and proper that the differences should be duly recorded. But is it right or advisable to bestow distinct specific names on animals so near to one another that it often requires the aid of a specialist to distinguish the one from the other? No one will deny that the lion and the tiger constitute a couple of well-marked species of the genus *Felis*. If, however, we trace the Indian tiger westwards into Persia and northwards into Central Asia, we find that it gradually assumes a longer coat, and either increases or decreases in size. Consequently, some zoologists regard the Siberian (and, for what I know, the Persian) tiger as a species distinct from the royal tiger of Bengal. Apart from the question whether the two intergrade in the intermediate area, if this view be adopted, we have now three species instead of two to deal with, namely the lion, the Bengal tiger, and the Siberian tiger; but it will be obvious that the two last differ from one another much less markedly than they both do from the first. If we only use English names, no very great harm is done, for we still see that two forms are tigers, while the other is a lion. In scientific nomenclature the case is, however, different, for each form receives a distinct specific name under the generic title of *Felis*; and hence there is no means of knowing by the nomenclature alone that two of the three are intimately related, while the other is widely different. Consequently, when we meet with the names *Felis tigris* and, say, *Felis sibirica*, and are told that the former is confined to India, we lose sight of the very important fcat that essentially the same type of animal ranges from Ceylon and India to the arctic tundras of Siberia; the difference in the length and thickness of its fur being obviously adaptations to its different climatic surroundings.

Precisely analogous instances occur in the case of the wolves and bears. The wolf of Europe is closely allied to the large American wolf, and very distinct from the coyoté, but if we separate the European wolf as one species, make several of the large American wolves, and several more of the coyoté, we have no clue to their mutual resemblances or differences; and we thus miss much important information about geographical distribution which ought to be apparent at first sight. Take, again, the deer allied to the red deer. The latter (*Cervus elaphus*) is a very distinct species confined to the Old World. In America it is represented by the wapiti (*C. canadensis*), which differs in colour, voice, and the form of its antlers. But there exists in Central and North-eastern Asia a deer so closely allied to the wapiti, that from the characters of the antlers alone the two cannot be separated. Now, if we regard this deer as a distinct species, under the name of *C. eustephanus*, we have obviously no means of knowing that it is much more nearly related to the wapiti than it is to the red deer, and we also lose sight of the circumstance that whereas the group to which the latter belongs is confined to the eastern hemisphere, the wapiti group is common to the north and north-eastern portions of both hemispheres.

But this is not all. By using specific terms in a wide sense the amateur zoologist and sportsman is able to keep in touch with the working zoologist, and thus to participate largely in the more important discoveries and advances of the science; whereas when specific distinctions are made on the minute differences now in vogue, he is utterly at sea, and probably throws up the whole study. Very likely the pure systematist may say that this is a matter of no moment, although this is not our own view.

What may be called the revolt of the amateur and sporting naturalist against the undue splitting of the modern specialist, has been initiated by Mr. Theodore Roosevelt, in an article in our contemporary *Science* for April 30, under the title of "A Layman's Views on Specific Nomenclature." Mr. Roosevelt, who holds the important office of President of the Board of Police Commissioners of New York, modestly styles himself a "layman," although he is really a very accomplished field naturalist, and probably knows more about the big game of North America than any other man. In this article the arguments are temperately, but forcibly put, the author laying stress on some of the points alluded to above, and urging that in the case of closely allied forms varietal or subspecific names should be employed in place of specific ones. Thus, the Asiatic wapiti should be a subspecies of the true wapiti, when its name (*Cervus canadensis eustephanus*) would at once indicate ts relationship. With regard to the use of specific names for what are essentially modifications of one and the same type of animal, Mr. Roosevelt writes as follows. "New terminology is a matter of mere convenience, and it is nothing like as important as the facts themselves. Nevertheless terminology has a certain importance of its own. It is especially important that it should not be clumsy or such as to confuse or mislead the student. Although species is a less arbitrary term than genus, still it remains true that it is more or less arbitrary. If one man chooses to consider as species what other men generally agree in treating merely as varieties, it is unfortunate, both because the word is twisted away from its common use, and

further because it confuses matters to use it in a new sense to the exclusion of the word commonly used in that sense. Moreover, it is a pity, where it can be avoided, to use the word so that it has different weights in different cases."

After calling attention to the great confusion and difficulty caused by the multiplication of species in genera which, in any case, contain a large number of specific forms, Mr. Roosevelt proceeds to make some very important remarks concerning genera which contain only one or two forms. He observes that—"The points of resemblance between beasts like the wolverines, the beavers, and the moose of the two northern continents are far more important than the points of difference. In each of these cases it does not much matter whether these animals are given separate specific rank, because in each case the Old World and the New World representatives make up the whole genus; but even here it would seem to be a mistake to separate them specifically unless they are distinguished by characters of more than trivial weight. The wapiti and Scotch red deer, for instance, are markedly different, and the differences are so great that they should be expressed by the use of specific terms. If the American moose and the Scandinavian elk are distinguished by specific terms of the same value, then it ought to mean that there is something like the same difference between them that there is between the red deer and the wapiti; and, as far as our present knowledge goes, this is not so. The wolverines, beavers, and moose of the two continents should only be separated by specific terms if the differences between each couple are of some weight, if they approximate to the differences which divide the red deer and the wapiti, for instance; and I know that even these two may intergrade."

With these sentiments we most cordially agree. Although we may prefer to regard each of the couples referred to as constituting only a single species, the harm done by dividing them is comparatively slight, not only, as Mr. Roosevelt states, because they are the sole representatives of their respective genera, but also from the fact that the members of each pair have the same English title; thus at once indicating their relationship and distribution.

If it be admitted that it is advisable to distinguish closely related forms from those more widely separated by means of nomenclature, the next question is whether it is preferable to do this by means of subgenera or subspecies. To illustrate this the case of the deer may be cited. By many writers of the present day the genus *Cervus* is taken to include all the deer furnished with brow-antlers, of which the wapiti is the only American representative. In this sense the genus may be split up into several subgenera, such as the Red Deer and Wapiti group (*Cervus*), the Japanese Deer group (*Pseudaxis*), the Fallow Deer group (*Dama*), the Sambar group (*Rusa*), and the Swamp Deer group (*Rucervus*) If we admit numerous species, we have in the first group the Red Deer (*Cervus elaphus*), the Barbary Deer (*C. barbarus*), the Maral (*C. maral*), the Wapiti (*C. canadensis*), the Asiatic Wapiti (*C. eustephanus*), &c. In the fourth we have the Sambar (*C. unicolor*), the Equine Deer (*C. equinus*), the Rusa (*C. hippelaphus*), the Hog Deer (*C. porcinus*), &c. Now, in the first group the Red Deer and the Maral are very closely allied, as are the true and the Asiatic Wapiti, and to retain these as species, and at the same time to express their true relationships, it is necessary to restrict the term *Cervus* to the Red Deer group, and to take the subgenus *Strongyloceros* for the Wapitis. This entails the raising of *Pseudaxis*, *Dama*, *Rusa*, &c., to the rank of genera. Similarly the Sambar, Equine, and Rusa Deer must form one subgenus of *Rusa*, and the Hog Deer a second. But this scheme has the disadvantage of splitting up the brow-antlered, or typical deer (*Cervus*) into several genera, which are much more closely related than is *Cervus* in its wider sense to the other usually accepted genera of the family, such as *Alces*, *Rangifer*, *Capreolus*, &c. We are, therefore, very little forwarder by this arrangement, by which we also lose sight of the fact that the brow-antlered deer (*Cervus*) are distributed over the greater part of the two northern continents, as well as India and the Malayan countries. On the other hand, if we adopt subspecies, the Maral becomes a subspecies of the Red Deer, as *C. elaphus maral*, and the Asiatic Wapiti of the true Wapiti as *C. canadensis eustephanus*, while the Equine and Rusa Deer respectively rank as subspecies of Sambar under the names of *C. unicolor equinus* and *C. unicolor hippelaphus*. Similarly, the Siberian ranks as a subspecies of the Indian tiger; while the brown and grizzly bears of Kamschatka and North America are ranked as subspecies of the European brown bear (*Ursus arctus*). Otherwise, the lion must be separated subgenerically from the tiger, and the brown and grizzly bears from the black bears. Which is the simpler, and, to most minds, the most philosophic arrangement, needs no mention!

Of course there are difficulties in such an arrangement, as there are in all sublunary matters; and in many cases there must and will be great difficulties in deciding as to what amount of difference constitutes a species and what a subspecies. But the same difficulty occurs when the term species is used in a more restricted sense. And it may be mentioned that even when so employed, subspecies are recognised by American writers. If it be necessary to indicate such "sub-subspecies," quadrinomials must apparently be employed, but these need only be mentioned for the benefit of the advanced specialist. The unfortunate thing in the matter is the existence of the "personal equation," which is one very difficult to get over. If, however, it be borne in mind when we have a large genus containing a number of well-defined types, around all or many of which cluster a series of closely related forms, that the term species be restricted to the former, while the latter are classed as subspecies, there ought in most cases to be no very great difficulty. In such an arrangement the amateur and the popular naturalist, as well as the student of geographical distribution in its wider and more important sense, can confine himself to the species, while the specialist can busy himself about the subspecies, or even the "sub-subspecies."

Possibly a greater latitude may have to be allowed to the students of the smaller mammals, such as the rodents, in which species may have to be based on slighter differences than are taken cognisance of in the case of the larger forms. Although perfect uniformity would be desirable, it is by no means absolutely essential that the same standard of distinction should be applied to all the groups.

As might have been expected, Dr. Merriam, one of the great champions of "splitting," has not allowed Mr. Roosevelt's challenge to pass in silence. And he has published a reply in *Science* of May 14, under the title of "Suggestions for a New Method of Distinguishing between Species and Subspecies." And here a moment's digression may be made to compliment both writers on the good feeling displayed in their criticisms—a marked contrast to some Transatlantic scientific disputations. Dr. Merriam states that hitherto he has taken the following as the distinction between species and subspecies, viz. that "Forms known to intergrade, no matter how different, must be treated as subspecies and bear trinomial names; forms not known to intergrade, no matter how closely related, must be treated as full species and bear binomial names." This is, of course, one of those hard-and-fast rules which look very nice on paper, but are not consonant with nature's system; for it is merely an accident whether the intermediate link is still existing, or has died out at a more or less remote epoch. In his new communication Dr. Merriam, for the first time, recognises the unimportance of the survival or extinction of the connecting link, and views with approval the proposal that our choice of binomial or trinomial nomenclature is to be governed by the *degree of differentiation rather than intergradation*. He expresses his new view as follows, viz. "In my judgment, forms which differ only slightly should rank as subspecies even if not known to intergrade, while forms which differ in definite, constant and easily recognised characters should rank as species even if known to intergrade."

It was not, of course, to be expected that Dr. Merriam would forthwith strike his flag, and admit that Mr. Roosevelt is right and himself wrong, but the giving up of the bugbear "intergradation" as a factor in the question at issue is undoubtedly a great point gained on the side of the "lumpers." It is, in fact, a clear admission that both species and subspecies are pure abstractions in the case of large genera, and that whether an animal is called one or the other is simply a matter of convenience. This being so, we may hope for the future to hear no more about such a creature being a "good" species.

The question of the distinction between species and subspecies is undoubtedly one bristling with difficulties, and it is therefore one which in many cases is incapable of being definitely settled by an individual opinion. Although personally convinced of the advisability of using specific names in a wide sense, and employing trinomials for the designation of the nearly related forms, it may be suggested that an international committee of zoologists should be formed to discuss the question

in all its bearings. Needless to say, such a committee should include representatives of both the "splitting" and "lumping" interests; and if the points at issue were fairly debated, with a full determination to give and take on both sides, it is difficult to believe that a working compromise between the extreme views could not be arranged. Almost anything is better than the present condition of uncertainty and discrepancy.

R. LYDEKKER.

RECENT INVESTIGATIONS INTO THE NUMERICAL VALUE OF "THE MECHANICAL EQUIVALENT."

THE value of the "mechanical equivalent," when deduced from experiments based on the direct transformation of mechanical work into heat, affords the best standard by means of which to test the validity of our system of electrical units. It is evident, however, that the value of this test depends upon the accuracy of the "equivalent" determinations. The engineer may (very rightly) regard extreme numerical accuracy in this case as comparatively unnecessary, but from the physicist's point of view there are few natural constants whose exact determination is of equal importance.[1]

Until the present time the evidence available has been so conflicting that it has been impossible to draw any certain conclusions from a comparison of the heat developed by mechanical work with that resulting from work electrically performed.

In *Phil. Trans. Roy. Soc.*, 1893, I gave an account of an investigation, by electrical methods, into the capacity for heat of water. The chief object of that work was to apply to the electrical units the test above referred to, for I considered that Rowland's admirable series of experiments (*Proc. American Academy*, 1879) on the direct conversion of mechanical energy supplied sufficient data to render such an investigation desirable. I regret, however, to say that, for the following reason, the results of that work have hitherto been of little value for the particular purpose for which it was undertaken. The change in the capacity for heat of water indicated by Rowland differed materially from that obtained by means of the electrical experiments. This difference in the rate of change must be due to differences in temperature measurements. In *Phil. Trans*, 1893, p. 496, I wrote as follows: "No change in the value of the various units or constants involved in our investigations could bring our results into absolute agreement with those obtained by Rowland, since, owing to the difference in the expressions for the temperature coefficients for the specific heat of water, it is inevitable that if our conclusions should agree at some one temperature, they must necessarily differ when expressed in terms of a thermal unit at any other temperature, and thus changes in the values of the units would only alter the temperature of agreement."

This quotation will, I think, render evident that but little progress could be made until some explanation of the discrepancies in the temperature measurements was forthcoming.

An indirect comparison of Rowland's standard with that of the Bureau International is given in Prof. Schuster's paper on the "Scale value of Dr. Joule's thermometers" (*Phil. Mag.*, 1895). The results indicate that Rowland's rate of decrease in the heat capacity of water would be diminished if expressed in terms of the International Standard; but, as Prof. Schuster remarked, "it would be necessary to have further information before any definite conclusions could be drawn."

I am glad to say that we are now in possession of the further information sought for by Prof. Schuster, and the above brief statement of our difficulties has been made in the hope of drawing attention to the new light now thrown on the whole subject.

[1] It has been decided (see Report of the Electrical Standards Committee, 1896) that the thermal unit is to be a dynamical one, hence the demand for accuracy becomes insistent.

Two entirely distinct investigations have just been brought to a successful conclusion in the laboratory of the Johns Hopkins University.

(1) "A recalculation of Rowland's value of the mechanical equivalent of heat in terms of the Paris hydrogen thermometer," by W. S. Day.

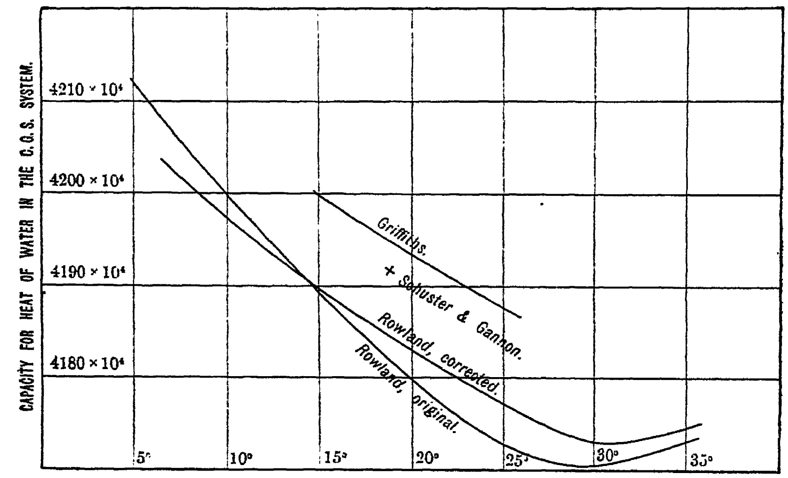
(2) "A comparison of Rowland's mercury thermometer with Griffiths' platinum thermometer," by C. W. Waidner and F. Mallory.

Both the above investigations have been carried out under the directions of Profs. Rowland and Ames. Full particulars of the work will shortly be published in America; but, in the meantime, the authors have very kindly given me permission to publish the results in this country. I will here give no details beyond the statement that the comparison of Rowland's thermometers with those of the Bureau International were made under conditions as nearly as possible similar to those prevalent during Rowland's experiments, and the same remark holds good with regard to the comparison with the platinum standard.

The results of these entirely separate investigations may be briefly summed up as follows:—

(1) The values resulting from Rowland's experiments undergo considerable modification at certain temperatures.

(2) Over the temperature range covered by Griffiths' experiments (14° to 26° C.), the rate of change in the capacity for heat of water becomes practically identical with that given by Griffiths.



(3) Throughout this range, Griffiths' value exceeds Rowland's by about 1 in 420.

(4) Separate standardisations of the same platinum thermometer were performed both in England and in America. The units adopted in the two cases differed slightly, but this is unimportant, as the temperature measurements are independent of the magnitude of the unit. The essential point is the respective values of the ratio of the resistance at 100° C. to that at 0°. These were as follows:

English	= 1·38596
American	= 1·38597

Thus affording satisfactory proof that not only the electrical measurements, but also the barometric standards, &c., are in perfect agreement.

(5) The results of the comparison with the platinum standard are (in the words of the authors) "in almost absolute agreement" with those deduced by Mr. Day from the direct comparison with the international standards, and thus the validity of Callendar and Griffiths' method of standardising the platinum thermometer is confirmed.

In the reduction of Rowland's results, "each individual experiment, the thermometers used in it, and the number of observations made with each thermometer, were taken into account.'

The results of all this labour are shown by the diagram (p. 258), and also by the following table.

Temp.	Old.	Corrected.	Griffiths.
10°	... 4200×10^4	... 4197×10^4	
15	... 4189	... 4189	... $4199{\cdot}7 \times 10^4$
20	... 4179	... 4183	... 4193·2
25	... 4173	... 4177	... 4187·4
30	... 4171	... 4173	
35	... 4173	... 4174	

Prof. Schuster and Mr. Gannon did not extend their determinations over any appreciable temperature range, and it is impossible, therefore, to apply the "rate of change" comparison to their results. Their thermometry, however, was directly based on the International Standard, hence it is probable that we now have *three separate determinations of the "mechanical equivalent" in which the temperature scale is identical.*

It appears to me that the data now at our disposal justify the following conclusions :—

(*a*) That the rate of change in the capacity for heat of water from 10° to 25° C. may be considered as known with sufficient accuracy for present purposes.

(*b*) That the persistent difference in the capacity for heat of water, when determined by mechanical and electrical methods, indicates a possibility that there is some error in one of the electrical units.[1]

One further matter deserves attention, concerning which there has hitherto existed considerable uncertainty, viz. the value of

the ratio $\dfrac{\text{“mean thermal unit”}}{\text{thermal unit at } t^{\circ}}$.

The value of this ratio is of great importance, as in the absence of exact information on this point we are unable to utilise the results of many notable experiments, such as those performed with Bunsen's calorimeter.

Until recently Regnault's value (1·005 in terms of the thermal unit 0° to 1°) has been universally adopted.

Some experiments performed by me in 1894, on the latent heat of evaporation of water, led to the conclusion that "the value of the 'mean thermal unit' is practically identical with that at 15° C." (*Trans. Roy. Soc.*, 1895, p. 320).

On the publication of this statement, Dr. Joly performed some experiments, from which we obtain the value ·9962 in terms of the thermal unit at 15° C. (*Phil. Mag.*, November 1895, p. 440), assuming Rowland's uncorrected values from 0° to 15°.[2]

In the Report of the Electrical Standards Committee, 1896, Mr. Shaw gives the results of a recalculation of Regnault's numbers, in which, assuming Rowland's uncorrected values, he obtains 1·0016 in terms of the thermal unit at 10°.

The enumeration of these facts indicates the extent of our uncertainty, and here again recent investigations lead us on to firmer ground.

In the Bakerian lecture delivered by Prof. Osborne Reynolds, on May 20, 1897, he communicated the results of an investigation by Mr. Moorby and himself into the value of the "mean thermal unit." Their results are of peculiar importance because they are practically independent of temperature measurements, and also on account of the large scale on which they were conducted. Their conclusion is "776·94 mechanical units at Manchester." I take this as equal to 777·07 at Greenwich = 4184×10^4 ergs. This is about equal to Rowland's corrected value at 19°, or, expressing it in terms of Rowland's corrected value at 15°, we get ·9988, which is sufficiently near to unity to justify my prediction as to the practical equality of the two units.

I trust that the above short summary will suffice to show that great advances have recently been made, and I venture to express a hope that the importance of extreme accuracy with regard to thermal measurements may, in the future, be more generally recognised than, I believe, has been the case in the past.

E. H. GRIFFITHS.

[1] For example, an error of 1 in 1000 in the electro-chemical-equivalent of silver would account for nearly the whole of our present discrepancies.

[2] I find that if we take Rowland's corrected values, this number approximates to ·9975.

THE ACTION OF LIGHT ON DIASTASE.

THE influence of the different rays of the solar spectrum upon the various phenomena of vegetable life has been shown by many observers to be not at all uniform. Speaking broadly, the rays lying to the left of the green, often collectively termed those of the red end, have been found to be most actively concerned with the metabolic processes. They are the ones on which generally the working of the chlorophyll apparatus depends, and in their absence no construction of carbohydrates from the carbonic anhydride of the air takes place. The rays beyond the green to the right, including also the ultra-violet ones, have, on the other hand, been shown to play but a small part in such constructive processes, but to be those on which the phenomena of heliotropism and other interferences with growth depend. They are broadly associated, therefore, with the physical rather than the chemical processes.

In recent years the influence of the blue, violet and ultra-violet rays has been found to be deleterious to vegetable protoplasm, exposure to them destroying many micro-organisms. They have further been shown to share, though to a small extent only, the power of assisting the chlorophyll apparatus. Some time ago a research of considerable importance was conducted by Messrs. Brown and Morris, from which it appeared that the amount of diastase obtainable from foliage leaves varies considerably at different periods of the day, being greater after darkness, and diminishing after exposure to light. An investigation of the action of the different rays of the spectrum on diastase has recently been carried out by Prof. Reynolds Green, which shows that its separate regions possess radically different powers, and that while some rays are beneficial and aid in the secretion of the enzyme, others are as distinctly deleterious and, indeed, affect the diastase in the same way as those of the blue end do the micro-organisms already spoken of.

By the use of appropriate screens the spectrum was divided into seven bands, the infra-red, the red, including the rays of wave-length $720\mu\mu$ to $640\mu\mu$; the orange, ranging from $640\mu\mu$ to $585\mu\mu$; the green, from $585\mu\mu$ to $500\mu\mu$; the blue, from $500\mu\mu$ to $430\mu\mu$; the violet, including the visible rays beyond wave-length $430\mu\mu$; and the ultra-violet.

Solutions of diastase, prepared from malt extract, and from the leaves of *Phaseolus vulgaris*, as well as from human saliva, were exposed to strong illumination, either that of the sun, or of a strong naked electric arc-lamp, for several hours, and after such exposure their hydrolytic power was tested side by side with that of control solutions that had not been illuminated. By the use of the screens already mentioned, the effects of these several regions of the spectrum were ascertained.

Of the infra-red, red, orange and blue regions the rays were found to have a distinctly beneficial effect upon the manufacture of the enzyme. The effect was, however, much the greatest in the red region, these rays, when allowed to act for ten to twelve hours, increasing the amount of diastase by one-half. A second maximum was obtained in the blue, while the rays of the other regions were intermediate in power.

The violet and ultra-violet rays were ascertained to exert a destructive action on the enzyme, an exposure of ten to twelve hours to the latter especially, often resulting in the destruction of 60 per cent. of the diastase. The change set up in the solution was found to be a continuous and progressive one, the extract becoming weaker after removal from the action of the light until the diastasic power entirely disappeared.

This effect was found to follow also a strong illumination of the living leaf. Leaves of *Phaseolus* were exposed to sunlight and the electric arc respectively, half of each being carefully shaded by a cover of blackened paper. After the illumination, weighed quantities of the shaded and unshaded sides were made to act under the same conditions upon a solution of starch, when the hydrolytic power of the unscreened portions was found to have been very materially injured.

The difference in the action of the various rays suggests a modification of the view that the chemical action of light in vegetable metabolism is particularly a property of the red end of the spectrum. This is borne out further by some experiments recently published by Laurent, who has found that the blue and violet rays are especially active in the construction of nitrogen-containing compounds in the plant. All the rays appear to be able to bring about chemical effects, the differences depending upon the materials taking part in the reactions, rather than upon any radical differences in the nature of the light.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Great Hall of the Northern Polytechnic Institute is being opened to-day (Thursday) by the Lord Mayor.

THE Rev. Dr. Thorburn, formerly Science Master in the Royal Grammar School, Sheffield, has been appointed Head Master of the Grammar School, Odiham, Hants.

THE sum of 2000*l.* has been offered to the Smith College for the erection of a building for the scientific laboratories, on condition that the sum of 1800*l.* is subscribed by the alumnæ.

DR. KARL TOLDT, Professor of Anatomy in the Medical Faculty of Vienna, has been elected Rector of the University for the Academic year 1897-98.

MR. C. A. MORTON and Dr. J. Swain have been appointed joint Professors of Surgery in the Faculty of Medicine of University College, Bristol.

A DONATION of 2500*l.* has been promised by Mr. A. F. Calvert to the funds of the proposed North-Western Polytechnic (St. Pancras and Hampstead).

ACTING on the recommendation of the Faculty of Physicians and Surgeons, Columbia University, the chair of Chemistry and Medical Jurisprudence (at present vacant) has been changed to that of Physiological Chemistry.

THE tenth session of the Marine Biological Laboratory, Wood's Holl, Mass., began on July 6, and is to last for six weeks. It is being conducted by Dr. B. M. Davis, of the University of Chicago, and two courses are offered, (1) on Elementary Botany, and (2) on the Morphology of the Algæ.

THE late Mr. J. S. Taylor, of Edderton, near Ross, left 4000*l.* in trust to found bursaries or scholarships to be known as the "John Taylor bursaries," to be competed for by natives of Thurso desiring to complete their education at Edinburgh University. He also bequeathed 1000*l.* to the Tain Academy, Ross-shire.

Science states that an anonymous donor has presented to the library of Columbia University 387 books, valued at about 1200*l.* They include a number of valuable works in natural history, such as Audubon's "Quadrupeds," Sepp's "Nederland'sche Insekten," Gould's "Humming-Birds," and Levaillant's "Oiseaux d'Afrique."

UNDER the will of Mrs. Gee, widow of the late Mr. Robert Gee, lecturer on the diseases of children in the medical school associated with University College, Liverpool, that college receives over 7000*l.* for the purpose of advancing the medical department, and promoting study and research in medical science. It has been decided by the medical faculty to institute a Robert Gee fellowship in anatomy of the value of 100*l.* for one year, and four entrance scholarships of 25*l.* each for one year.

THE following appointments are announced:—Dr. Thomas S. Fiske, of Columbia College, has been made a full Professor of Mathematics; Dr. Wm. Slocum, at present President of Colorado College, has been elected President of Oberlin College; Dr. G. Boccardi has been appointed Associate Professor of Microscopical Anatomy at the University of Naples; Dr. J. Szadowski, Associate Professor of Geology at the University of Klausenberg; and Dr. J. J. Zumstein to be Professor of Anatomy at the University of Marburg.

A MEETING of the subscribers to the Hall Memorial Fund, which was started a few months ago to commemorate the jubilee of science teaching at the City of London School, was held at the school on Monday last. It was announced that the amount subscribed (including 100 guineas from the Corporation) was about 354*l.*, and it was resolved that 350*l.* should be devoted to founding a scholarship to promote the study of chemistry and physics in memory of the late Mr. T. Hall, science master at the school, 1847-1870. The scholarship is to be awarded every fifth year, and to be tenable for two years.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. xix. 3.—Development of the A-process in quaternions, with a geometrical application, by Dr. J. B. Shaw, gives several interesting results.—On the analytic theory of circular functions, by A. S. Chessin. The writer points out that the similarity between simply and doubly periodic functions ceases to exist when the behaviour of the function at infinity comes to be investigated. He refers to M. Méray's "Leçons nouvelles sur l'Analyse infinitésimale et ses applications Géométriques," wherein is given a classification of simply periodic functions into *polarised* and *non-polarised* functions. He then states that the character and *rôle* of the *polar values* of a circular function have not been clearly set forth, and that the object of his paper (pp. 216-258) is to supply the deficiency.—Sur un problème concernant deux Courbes Gauches. by Prof G. Kœnigs. The problem, of which a *direct* solution is given, is "une Courbe C étant donnée, en trouver une autre C, qui lui corresponde point par point de sorte que le plan osculateur à chaque courbe aille passer par le point qui correspond sur l'autre au point de contact."—The object of a second paper, by Dr. Shaw, entitled "The Linear Vector Operator of Quaternions," is the development of the linear vector operator, entirely from a quaternion point of view, which amounts, the author writes, to an extension or development of nonions; reference is made to a paper by Dr. H. Taber in vol. xii. of the journal.—On certain applications of the theory of probability to physical phenomena, by Dr. G. H. Bryan. This is a subject to which much has been contributed in our columns. Dr. Bryan arrives at the conclusion that even the theory of probability does not furnish us with a *conclusive* proof of the Boltzmann-Maxwell law. That the law in question represents accurately the state of the molecules in a perfect gas, and approximately their state in an ordinary gas, cannot be doubted; but directly we attempt to generalise the law by applying it to assemblages of densely crowded molecules, we are confronted with the necessity of making some assumption or other, and the above treatment (*i.e.* employed in Dr. Bryan's note) shows that even probability considerations do not afford a sure way out of the difficulty.

MESSRS. W. AND G. S. WEST's paper on Welwitsch's African Freshwater Algæ is still occupying the pages of the *Journal of Botany*, with the description of a large number of new and interesting forms. In the numbers for June and July descriptions are given of the following new genera: *Athroocystis*, belonging to the Palmellaceæ; *Camptothrix*, the type of a new order, *Camptotricheæ*, of Cyanophyceæ; *Polychlamydum*, near to *Schizothrix*.—Mr. E. G. Baker describes and figures the variety *ceratophyllon* of *Plantago coronopus*, new to Britain.—Mr. Arthur Lister has some notes on rare species of Mycetozoa, in which several new species are described.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 17.—"On the Distribution of Frequency (Variation and Correlation) of the Barometric Height at diverse Stations." By Prof. Karl Pearson, F.R.S., University College, London, and Miss Alice Lee, B.Sc., Bedford College.

This paper is especially intended as an *illustration of method*. The authors believe that hitherto no exact theory of variation or of correlation has been applied to meteorological observations, and they have endeavoured to indicate that fruitful results may be obtained from such a theory when applied to one branch at least of meteorology, namely, barometric frequency.

Their first object was to determine the nature of the barometric frequency distribution. By means of tables and plates it is shown that it can be described with a very high degree of accuracy by the use of a generalised frequency curve of the type—

$$y = y_0\left(1 + \frac{x}{a}\right)^p e^{-\gamma x},$$

a type which has been fully discussed in a previous memoir on skew variation.

A standard frequency curve for the British Isles having been selected, it is shown that the frequency distribution varies continuously from this type as we pass from station to station, and appears to be fairly uniform along lines which are termed generalised isobars.

The authors' next object was to discover what constants of the barometric frequency suffice to describe it with the least probable error. A somewhat elaborate investigation was accordingly made into the probable errors of the constants, and four *physical* quantities, the mean, the variation (or standard

deviation), the skewness, and the modal frequency were found to be the constants, which described a local barometric frequency with the smallest probable errors.

They have next discussed the chief physical features of a barometric frequency distribution.

(*a*) The modal height and the modal frequency are found to possess certain advantages over the mean height and the mean frequency. Various methods are considered for approximately determining the position of the mode.

(*b*) The variability of the barometric height and the skewness of the distribution are discussed at some length.

(*c*) A test of the accuracy of the observations for the twenty coast stations is made by attempting an interpolation of the frequency constants of London and Cambridge between those of Southampton, Hillington, and St. Leonards.

In the second part of the memoir the subject of correlation is dealt with. It is shown that within the limits of the British Isles there is a very high degree of correlation (as high as 0·9824 between Babbacombe and Churchstoke), and only sinking to 0·7572 if we take practically the utmost reach of the British Isles. It is pointed out that the gradual change of correlation with direction and distance, combined with change owing to the interval of time between observations, enables the meteorologist to find systems of stations with almost every variety of correlation coefficient.

The probable height and probable deviation from that height at any given station, based on a knowledge of the heights, contemporaneous or not, at one, two, three, or more other stations, are considered. It is indicated that with proper arrangement of times and distribution of stations it must be possible to make the probable deviation zero or nearly zero, and hence to predict with very great accuracy the height at one station from a knowledge of heights at other selected stations. The suggestion is made that this principle might very possibly be applied to closely predict future barometric heights at a given station from antedated observations at other selected stations.

Various theorems are deduced from the general principles of correlation: thus, it is shown that—

(*a*) There is a balance height for every pair of stations, such that when the barometer stands above this height at one station it will usually stand below it at the other, and *vice versâ*.

(*b*) That for a very considerable number of triplets of stations which are positively correlated together, so that a high barometer at one means usually a high barometer at a second, it can still be predicted that if the barometer be steady at one, a rise or fall at the second denotes a fall or rise respectively at the third member of the triplet.

The writers hope that their paper may draw attention to the importance of rendering the large amount of barometric observations now made, available for the easy calculation of the variation and correlation coefficients. They consider that if a chain of stations round a large continental area could have their correlation for a series of intervals of time worked out, much might be done in the way of very close prediction of barometric changes.

"On the Theory of the Magneto-Optic Phenomena of Iron, Nickel, and Cobalt." By J. G. Leathem, Fellow of St. John's College, Cambridge. Communicated by Sir Robert S. Ball, F.R.S.

In this paper the fundamental equations of a particular type of magneto-optic theory are taken in a general form on the lines of Mr. Larmor's recent papers on electro-dynamics, and developed so as to obtain the solutions of the problems of magnetic reflection and of transmission through films. The formulæ so obtained are compared with the available experimental results.

The notation differs slightly from that of Maxwell: C denotes the velocity of radiation, and (f'', g'', h'') corresponds to Maxwell's total electric displacement; this has components (f, g, h) and (f', g', h'), of which the former is the displacement involved in the ether strain, and the latter that involved in the polarisation of the matter. It being assumed that for light oscillations the magnetic permeability is unity, the fundamental equations of the theory are as follows: (i.) The circuital relations $dc/dy - db/dz = 4\pi u$ and $dR/dy - dQ/dz = -da/dt$. (ii.) The equations of the current $u = \sigma P + g_3 Q - g_2 R + df''/dt$, where the vector (g_1, g_2, g_3) represents the Hall effect. (iii.) The displacement relations, and the elastic relations between electromotive force and polarisation, viz. $f'' = f + f'$, $f = P/4\pi C^2$, and $f' = (K - 1)/4\pi C^2 . P + b_3 dQ/dt - b_2 dR/dt$, the vector (b_1, b_2, b_3) representing, in transparent matter, the whole magneto-optic effect.

The vector $\{(b_1 d^2/dt^2 + g_1), (b_2 d^2/dt^2 + g_2), (b_3 d^2/dt^2 + g_3)\}$ is assumed equal to $C_0 e^{\iota x} (\alpha_0, \beta_0, \gamma_0)$, where $(\alpha_0, \beta_0, \gamma_0)$ is the intensity of magnetisation; and $C_0 e^{\iota x}$ is the single magneto-optic constant of the theory.

The principal experiments made use of are those of Drs. Sissingh and Zeeman on magnetic reflection, their observations being measurements of the phase m and amplitude μ of the "magneto-optic component" of the reflected light for various angles of incidence.

The following table will serve to indicate what sort of agreement is found to exist between the theory and the experiments.

Equatorial Reflection from Iron.

Angle of incidence.		Observed value of m.		Calculated value of m.
° ′		° ′		° ′
86 0	...	209 26	...	272 35 − x
82 30	...	204 22	...	265 19 − x
76 30	...	194 49	...	256 31 − x
71 25	...	190 3	...	251 13 − x
61 30	...	181 49	...	244 18 − x
51 22	...	179 0	...	239 48 − x
36 10	...	174 9	...	235 27 − x

If the value of x is about 62°, the agreement shown is remarkably good. Experiments on polar reflection from iron point to almost exactly the same value for x.

If we suppose the value of C_0 to be given by

$$-C_0 = 7 \cdot 283 \times 10^{-11},$$

the ratios of the calculated to the observed values of μ for the above angles of incidence are found to be respectively 1·13, 0·96, 0·99, 0·97, 1·01, 1·03, and 0·97; so that in the case of the amplitudes also there is good agreement.

The theory gives a satisfactory account of a phenomenon which has only recently been discovered, namely, an effect of the component of magnetisation perpendicular to the plane of incidence. Good agreement is also found to exist in the case of the experiments on transmission through films.

It is to be noticed that, as b_1, b_2, b_3 are necessarily real, the imaginary part of $C_0 e^{\iota x}$ must be entirely accounted for by the Hall effect. Hence the present theory involves the supposition that the Hall effect is very much greater for rapidly alternating currents than for steady ones.

"On the Change of Absorption produced by Fluorescence." By J. Burke, M.A. (Dub.).

A careful series of experiments which have led to the result that certain fluorescent substances—notably uranium glass—absorb the rays which they give out whilst fluorescing differently, according as they are in a state of fluorescence or not; so that if a body, A, of some fluorescent substance, such as uranium glass, be transmitting light from a similar body, B, which is fluorescing the amount of light transmitted by A from B, is quite different, according as A is fluorescing or not.

If α and β are the coefficients of transmission in the two cases for uranium glass 1 cm. thickness, the mean values obtained by eye observation are $\alpha = 0 \cdot 47$; $\beta = 0 \cdot 79$.

The ratio $\dfrac{\beta}{1 + \alpha}$ was also independently determined, the mean value of which $= 0 \cdot 507$. The values of α and β determined photographically were

$$\alpha < 0 \cdot 48 \qquad \beta > 0 \cdot 75$$
$$> 0 \cdot 43 \qquad < 0 \cdot 89$$

In the determinations of α and β, a null method has been employed, by which any appreciable want of uniformity in the illumination could be detected.

The source of illumination was almost invariably the spark discharge of a Leyden jar between cadmium electrodes, being one of the richest sources of the fluorescence exciting rays, and the photometer one specially constructed for the purpose.

The phenomenon has been exhibited directly by obtaining two photographs side by side upon the one plate: one the effect of the fluorescence due to two layers of the fluorescent substance; the other the result of superposing the effects due to the fluorescent light from a single layer according as it came directly or through a non-fluorescing layer of equal thickness. The exposures being equal in each of the three cases, the superposed photographic effect was greater than the other one,

notwithstanding the fact that the result of superposing two nearly equal effects due to light of the same intensity—or nearly so—had been found not to be equal to, but less than that due to light of double the intensity acting for half the time. If the resultant effect were equal to the sum of the separate ones, the effect caused by the change of absorption would have been still more marked.

The effect can also be shown by the photometer, for if $a = B$, taking the maximum value of $a = 0{\cdot}48$, the ratio $\frac{a}{1+a} = 0{\cdot}32$, and instead of obtaining equality when the photometer is adjusted for this value the difference is most marked.

"On the Relative Behaviour of the H and K lines of the Spectrum of Calcium." By William Huggins, D.C.L., LL.D., F.R.S., and Mrs. Huggins.

The problem before us was to find out by experiments in the laboratory, under what conditions the lines of calcium other than the lines H and K, and in particular the strong blue line at 4226·9, were so greatly enfeebled relatively to H and K, that they became quite insignificant, or even disappeared altogether from the spectrum, leaving the very simple spectrum of the two lines H and K, or nearly so.

It was suggested to us by the known rarer state of the gases in the regions above the photosphere, as well as by my long experience with the behaviour of calcium in comparison spectra, that the modifications of the calcium spectrum which we were seeking, would be likely to show themselves under conditions of greatly reduced density of the calcium vapour.

For obvious reasons we elected to use throughout the experiments a spark of very small intensity.

Our expectations were completely confirmed. Under the conditions (*a*) of greatest density of the calcium vapour, when metallic calcium was employed, the blue line was as strong and possessed the same diffuse character as H and K.

As the density of calcium was reduced, the lines were not found to be equally enfeebled, but, on the contrary, the blue line and the greater number of the lines were increasingly reduced in intensity relatively to H and K, until at last with the twice washed electrodes (*d*) the spectrum was simplified to the condition usually existing in the prominences, in which H and K only are present.

A more precise statement of the changes of relative intensity as they are presented in the photographs on the plates are given in the paper.

The only condition which was varied during this set of experiments was the amount or density of the calcium vapour. The changes of relative intensity, and the modifications of the calcium spectrum produced thereby, correspond closely to the behaviour of calcium at different levels near the sun's limb, and in the atmospheres of stars of different orders. There can remain little doubt that the true interpretation of the changes in appearance of the calcium lines in the celestial bodies is to be found in the different states of density of the celestial gases from which the lines are emitted or by which they are absorbed.

In the modifications of the calcium spectrum arising from variations in the relative intensities of the lines which have been discussed in this paper, and which correspond to those observed in the celestial bodies, there does not appear to us any reason for assuming, much less any direct evidence in favour of, a true dissociation of calcium, that is, of its resolution into chemically different kinds of matter.

A letter from Prof. Liveing is added, which contains an account of early experiments on the spectrum of calcium which support, by a different method of working, the conclusions of our paper; and seem to show the possible occurrence of the line H without K. In our experiments both H and K were always present, K being stronger than H, as is the case in the photographs of the prominences by Hale, and by Deslandres.

"Stress and other Effects produced in Resin and in a Viscid Compound of Resin and Oil by Electrification." By J. W. Swan, F.R.S.

In this paper are described the stress and other effects produced by non-luminous electrical discharges on a viscid mixture of resin and oil. Wires from the discharging terminals of an induction coil or Wimshurst machine were led, one above and the other below a glass dish containing the resin mixture. The terminal above the resin surface was usually a point, ball, or disc, and the one below was a disc, forming a support for the dish of resin. The discharging arms of the coil were used as a spark gap. The spark, 25 to 50 mm. long, always passed at the spark gap, the terminals above the resin being so adjusted that the resistance to discharge was slightly greater there than at the spark gap. When the upper terminal is a ball, and connected to the + electrode, then on a spark passing at the spark gap there is produced on the surface of the viscous mixture a star-shaped figure, formed of deeply-furrowed, closely-clustered, outward-branching rays, extending from a circular frill near the centre to the margin of the dish. The figure gradually dies down, and when the surface is smooth it may be produced again and again.

If the terminal above the resin surface be made − instead of +, then on a spark passing at the spark gap, a figure characteristic of the − discharge is produced. This figure is much smaller and weaker than the + one; most frequently it consists of a circular band or ring, more or less indented in outline, enclosing leaf-like rays which tend towards the centre. These are relatively broader and less branching than the + rays, and are in relief, while the + rays are below the plane of the surface. When the electrification is strong, the ring enclosing the rays stands up as a frill in considerable relief. These figures closely resemble the dust figures obtained by Lichtenberg and Armstrong.[1]

The character of the figures depend on

(1) Whether the terminal over the dielectric is + or −.
(2) The form and size of the + and − terminals.
(3) The distance of the upper terminal from the surface of the dielectric.
(4) The character of the spark at the spark gap.
(5) The density of the atmosphere.

Permanent figures may be obtained by substituting ordinary hard resin for the viscous mixture. The figures are then developed by warming and rendering the surface sufficiently plastic to allow of movement. The persistence and fixity of the stresses produced by a discharge on resin is remarkable, figures have been developed two months after the discharge with very slight diminution of effect.

The density of the atmosphere exercises a great effect on the figures obtained. As the density diminishes, the figures become more diffuse and less marked in character, and at an air pressure of 85 mm. a + figure becomes faintly marked by bands without the characteristic rays.

Geological Society, June 23.—Dr. Henry Hicks, F.R.S., President, in the chair.—Notes on a collection of rocks and fossils from Franz Josef Land, made by the Jackson-Harmsworth Expedition during 1894-96, by E. T. Newton, F.R.S., and J. J. H. Teall, F.R.S. A large collection of rocks and fossils, obtained by the members of the Jackson-Harmsworth Expedition, chiefly from the neighbourhood of Cape Flora, on the south-west of Northbrook Island, but also from more distant localities visited during boat- and sledge-journeys, have been sent to the Director-General of the Geological Survey, and examined by the authors. After a summary of what was previously known of the geology of Franz Josef Land, an account of the new specimens was given. The rocks are for the most part basalts, and are described in detail; they are usually formed of labradorite, augite, and interstitial matter which is sometimes represented by palagonite containing a large percentage of iron-oxide. This palagonite is regarded as the hydrated representative of the residual magma left after the separation of labradorite and augite; and the conclusion is reached that in this case progressive crystallisation has resulted in the concentration of iron-oxide in the mother liquor. Most of the fossils have been collected around Cape Flora. The presence of *Ammonites macrocephalus*, *A. modiolaris*, and *Belemnites Panderi* indicate the presence of rocks of Lower Oxfordian or Callovian age; while, apparently above these, a plant-bed was met with in which the genus *Ginkgo* is conspicuous, and this is believed to be of Upper Jurassic age. The oldest fossiliferous bed yet found occurs about twenty miles to the west of Cape Flora, and also contains plant-remains, which, it is thought, may be Lower Jurassic and possibly of the age of the Great Oolite. These plant-beds and numerous indications of layers of lignite seem to show that these Jurassic strata are to a great extent of estuarine or fresh-water origin. The general structure of the country appears to be typified by what occurs at Cape Flora, where cliffs of sedimentary strata some 600 feet high (for the most part hidden

[1] "Electric Movements in Air and Water, with Theoretical Inferences." By Lord Armstrong, C.B., F.R.S. (London: Smith, Elder, and Co., 1897.)

by talus) are overlain by 500 feet of basalt. At some other localities, however, the basalt is found at the sea-level. It is pointed out that the islands, which make up the archipelago of Franz Josef Land, are fragments of a formerly extensive region of plateau-basalts, similar to that of which the Færöe and the Western Isles of Scotland must have formed a part.—Deposits of the Bajocian age in the North Cotteswolds. Academy of Sciences, July 5.—M. A. Chatin in the chair.—The elections of M. Hatt, as Member of the Section of Geography and Navigation, and of M. de Lapparent, in the Section of Mineralogy, were confirmed by the President of the Republic.—Distribution of the velocities of gradually varied flow in tubes of large section, and the equation of the motion to a higher degree of approximation, by M. J. Boussinesq.—On the explosion of a manometer in a projection apparatus, by M. de Lacaze-Duthiers. The manometer in question had been used without accident on many previous occasions, and no explanation can be offered to account for its bursting, which was attended with serious injury to the lantern manipulator. The question was referred to a committee for investigation.—M. Virchow was elected a Foreign Associate of the Academy in the place of the late M. Tchebichef.—On the establishment of a general formula of interpolation for functions of any number of variables, by M. Dupont.—On the algebraic surfaces which admit of a skew cubic as an asymptotic line, by M. Ch. Bioche.—On the partial polarisation of luminous radiations under the influence of the magnetic field, by MM. N. Egoroff and N. Georgiewsky. The experiments show that the luminous intensity of a Bunsen burner always increases under the influence of a magnetic field. By the aid of a Wollaston prism it was found that a magnetic field partially polarises each of the rays of the sodium spectrum in two perpendicular planes. The fine lines of the metalloids, obtained by M. de Gramont's method, remain unchanged in the magnetic field.—The magnetic deviation of the kathode and X-rays, by M. G. de Metz. In a previous paper certain effects were attributed to the kathode rays, which M. Poincaré suggested might really be due to X-rays, the latter being possibly produced by the reflection of the kathode rays at a platinum surface. Preliminary experiments upon the behaviour of the reflected kathode rays towards a magnet tended to show that X-rays were not produced under these conditions, but further researches seem to indicate that the two classes of rays cannot be distinguished by their behaviour towards a magnet.—On the actino-electric effects of the Röntgen rays, by M. S. Puggenheimer. If two similar electrodes are plunged into a liquid and exposed to the Röntgen rays, a current is set up in the wire joining the plates, the intensity and direction of which depends upon the intensity of the radiation.—On a thermal ammeter containing mercury, by M. Charles Camichel. The bulk of a mercury thermometer is placed concentrically in a glass tube containing mercury; the current is passed through the latter for a definite time, and the rise of temperature read. It is shown that for a constant current the rise of temperature is constant, moderate variations of the air temperature being without effect upon the readings.—New mercury pump without taps or mobile joints, by M. H. Henriet. The pump figured appears to be practically identical with the original form of the Töpler pump, except that the side tube for admitting air without bumping to the vacuous vessel is omitted.—Action of tellurium chloride and fluoride upon the corresponding hydracids, by M. R. Metzner. The compounds $TeCl_4.HCl.5H_2O$, $2TeF_4.3TeO_2.6H_2O$, and $TeF_4.TeO_2.2H_2O$ were prepared and analysed.—Reduction of molybdic acid by hydrogen, by M. M. Guichard.
